artiodactyl species. Artiodactyl reproductive strategies are widely varying among species and often relate directly to social structure and availability and distribution food and space resources (Geist 1981). Body mass, gestation length, and growth rate may be an important driver of parental care and thus reproductive strategies in artiodactyls, with greater investment in a smaller number of offspring dictating the design of the species' mating system (Saether and Gordon 1994). Therefore, reproductive strategies in this group of species are directly tied to the amount of energetic investment required to successfully reproduce.

Parental care is essential for the survival of many species, but a key component in maximizing fitness of many  $k$ -selected (i.e., long-lived with limited reproductive output) ungulates. Maternal care in ewes (*Ovis* spp.) has been shown to be driven by a release of oxytocin during parturition, which cues the increase of neurotransmitters necessary to initiate maternal instinct for care (Dwyer 2013). This naturally orchestrated course of events results in the acceptance of the lamb by the mother, often expressed in the form of licking, low bleating, udder acceptance, and suckling. This maternal behavior is reserved for the singular lamb.

Most artiodactyl species breed during a single reproductive season. Thus, competition for mates can be severe and depends on distribution of females and resources in the environment. Despite variation in levels of parental care, few artiodactyl species are monogamous. More typical are forms of female defense polygyny, resource defense polygyny, or harem polygyny. In female defense polygyny, males will compete directly for females and defend them while in estrous but will move on to other females once the estrous period has ended. In resource defense polygyny, males will defend critical resources utilized by females to secure mates in an area, and in harem polygyny, males will defend multiple females (e.g., a harem) within a territory and mate with each female in estrous. Topi (*Damaliscus lunatus*), found in the savannas of Africa, are known to defend resource territories, which may reduce male-male competition for mates. However, if groups of females are

mobile and concentrated, males will shift held territories, aggregate together, and begin to exhibit lekking behavior, which includes clustering of males simultaneously competing for females in a small area (Gosling 1991). Thus topi adopt a mixed reproductive strategy that is adaptive to spatial distribution and availability of females.

## Social Order in Artiodactyls

The social order of animals is a widely studied subdiscipline of animal behavior, and the literature is ripe with research on social organization of artiodactyl species. Pigs begin to display social order when they are newborn, forming a hierarchy while suckling and commonly resulting in aggressive behaviors among litter mates. Competition to suckle in the middle teat is more intense than any other location (Skok et al. 2014). Agonistic behavior such as "head butting" and antler locking in males within social groups is common display of aggression and competition among many artiodactyl species and often relates to dominance and social order. Species such as mountain goats (*Oreamnos americanus*), musk deer (*Moschus chrysogaster*), and others have been observed exhibiting similar social hierarchy behaviors. Social hierarchy often includes dominance in artiodactyl social groups. For example, dominant members of horned Japanese black cattle (*Nihon tankaku washu*) groups have been observed laying closer to hay racks in pastures than their subordinate counterparts, excluding access to other members within their social hierarchy (Nakanishi et al. 1992). Relatedness often plays a role in social structure of many artiodactyl species. For example, collared peccaries (*Pecari tajacu*) are a highly social artiodactyl with spatial association of groups directly related to high levels of relatedness, but not necessarily degree of social interaction (Biondo et al. 2014). Similar patterns of kinship and familiarity have also been shown in hippopotamus (*Hippopotamus amphibius*), along with potential for nonlinear dominance hierarchies (Blowers et al. 2010).

## Resource Allocation/Foraging Strategy

Availability and distribution of food, water, shelter, and other resources play an important role in the life history of artiodactyl species. These factors influence the ways in which a species seeks resources and the mechanisms they use to obtain them. Distance, in combination with accessibility and distribution of resources, affects many facets of life history, including social structure, mating system, migration, and ultimately fitness. For example, white-lipped peccaries (*Tayassu pecari*), a tropical ungulate, exhibit a group-foraging strategy that facilitates location of nonuniformly distributed fruit, seed, and water resources. This involves a combination of strategies, including periods of intense foraging in one area and/or foraging forays over longer distances. The outcome of this mixed strategy is varying degrees of movement among distributed resources in different areas (Reyana-Hurtado et al. 2012).

Many artiodactyl species play a distinct role in the physical makeup of their environment while carrying out elements of their life history. Species affect growth and dispersal of vegetation in their environment by foraging, stomping, urinating, and defecating. The link between species and vegetation is undeniable making the study of foraging behavior in animals important. Scottish black face sheep (*Ovis aries*) and European red deer (*Cervus elaphus*) spend a considerable amount of time (about 50% of their day) grazing on heather and grass in their natural habitats. However, both species prefer grass over heather during the growing season, which may influence the proportional distribution of grasses compared to heather in the landscape (Hester et al. 2001). Thus artiodactyls, by nature of their herbivory, may drive as well as be driven by the distribution of forage resources in an area.

## Conclusion

Artiodactyls represent a widely varying group of mammalian species with life histories highly adapted to maximize survival and fitness in the sometimes challenging environments they

inhabit. Selection of resources, degree of movement, foraging strategy, reproductive strategy, longevity, and a host of other factors characterize life histories for each of the artiodactyl species. In general, Artiodactyla are relatively long-lived, *k*-selected (lower reproductive output) species, often with large body masses relative to other mammalian orders. They are also adapted to survive in a range of conditions, with specific measures for water conservation, heat reduction or insulation, and foraging success all key parts of their life history characteristics.

## Synonyms

Cloven-hooved mammal locomotion; Even-toed ungulate locomotion

## Definition

Movement used by artiodactyls (even-toed ungulates) to traverse their environment.

The Artiodactyla, or even-toed ungulates, are an order of hooved mammals that are known to bear weight and ambulate on the third and fourth digits. The order of Artiodactyla can further be

divided into the suborders of *Tylopoda* (camels, llamas, guanacos, alpacas, and vicuñas), *Suina* (pigs and peccaries), *Ruminantia* (cattle, goats, sheep, deer, and antelope), and *Hippopotamidae* (hippopotamus) as well as several other species. Sisters to the artiodactyls are the perissodactyls, or odd-toed ungulates, consisting of horses, rhinoceros, and tapirs. Over 220 different species of artiodactyls have been found around the globe, and new subspecies are continuously being described. Artiodactyls are found throughout a variety of habitats worldwide but are not native to Australia, Antarctica, or oceanic islands, despite being successfully introduced to Australia and numerous islands (Cope 1888; Grzimek et al. 2003; Rose 1996).

Artiodactyls are mainly terrestrial herbivores and live within four different general habitats. These include open grasslands, grasslands and meadows, steep cliffs, forests, shrubland, and an intermediate habitat between forests and open lands. Each habitat provides its own unique advantages; steep cliffs provide security, grasslands allow for widespread vision to avoid predators, and forests are full of cover and vast vegetation. The Artiodactyla order is made up of animals with an abundance of different shapes, sizes, tendencies, and most importantly locomotion behaviors (Grzimek et al. 2003).

## Gait Sequences

Gait is the manner a species utilizes to traverse through terrain (Hildebrand 1977). Gait can first be divided into symmetric, in which the footfalls of the forelimb and hindlimb are separated evenly in time, and asymmetric, in which the footfalls of the forelimb and hindlimb are separated unevenly in time. Symmetric gaits are observed during walking, pacing, and trotting, while asymmetric gait are seen during galloping or bounding.

A walking gait is one with a duty factor greater than 50%. Duty factor refers to the percentage of the cycle during which a foot is contacting the terrain. The center of mass (COM) is comparable to a swinging inverted pendulum during walking gaits, as energy flows between kinetic and

potential in synchrony with the rise and fall of COM during each stride. When walking, mammals either do so in a lateral-sequence, during which each hindlimb footfall precedes an ipsilateral forelimb footfall, or a diagonal-sequence, during which each hindlimb footfall precedes a contralateral forelimb footfall. Furthermore, a couplet is that in which two limbs move together; a diagonal couplet refers to contralateral hindlimb and forelimb moving together, while a lateral couplet refers to ipsilateral hindlimb and forelimb moving together. Although these limbs may be traveling together, it is important to note that they almost always do so in slight asynchrony (Hildebrand 1989).

Walking gait patterns in the artiodactyls include the lateral-sequence lateral-couplets and lateral-sequence diagonal-couplets (Fig. 1). Lateral-sequence lateral-couplet walking occurs when ipsilateral forelimb and hindlimb move together, with the hindlimb footfall preceding forelimb footfall. Such a gait sequence is observed among long-legged artiodactyls such as the giraffe, but may be too unstable for short-legged mammals. Such instability is a result of lateral body-roll, as the trunk of the body is only stabilized by the opposite two limbs during each stride

**Artiodactyla Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in Artiodactyla ( $n = 34$  species)

(Granatosky 2018). A lateral-sequence diagonal-couplet gait sequence occurs when each hindlimb footfall precedes that of the ipsilateral forelimb, but contralateral hindlimb and forelimb move with one another. Such a sequence provides better stability for short-legged mammals, such as the pigs and peccaries, as they spend much less time as unilateral bipods during each stride compared to lateral-sequence lateral-couplet gaits. The diagonal axis in which contact is made with the ground prevents the body-roll commonly seen with lateral-sequence lateral-couplet gait (Granatosky 2018).

A running gait is one with a duty factor less than 50%. A mammal's COM is comparable to a bouncing ball during running gait, as movements occur in phase with each other (Granatosky 2018). The artiodactyls utilize several different running gaits across their order, including the symmetrical trot and pace, and the asymmetrical gallop and pronk. As per Hildebrand (1989), the trot is the most stable of all running gaits. A trot is observed as contralateral hindlimb and forelimb stride synchronously. Hildebrand (1989) defines the pace as a running gait during which the ipsilateral hindlimb and forelimb stride synchronously. Like that of the lateral-couplet, the pace may pose some stability issues for short-limbed mammals as they spend time as unilateral bipods during such a gait. Artiodactyls such as the camels take advantage of the pace, as it prevents possible collision of ipsilateral limbs during running gait.

At higher speeds, artiodactyls transition to a gallop (Granatosky 2018). A gallop is observed when a mammal's running gait utilizes a leading foot of both the fore and rear limbs. A leading foot refers to the fore or hind limb that contacts the ground after its respective contralateral counterpart and is further ahead at time of contact. The limb that strikes the ground first and further behind is then referred to as the trailing foot (Hildebrand 1989). Artiodactyls are known to perform both forms of galloping; the first being a transverse gallop in which the leading fore and hind limbs are ipsilateral, and the second being the rotary gallop, often seen in *Suinae* (Datt and Fletcher 2012), in which the leading feet are on contralateral sides. Artiodactyls such as the pronghorn antelope also practice what is known as straddling, during which the hindlimbs are placed before and outside of the forelimbs. Doing so allows for these animals to traverse quickly without possible physical interference between the forelimbs and hindlimbs (van der Sluijs 2004).

An interesting gait sequence unique to the artiodactyls is the pronk or stott (Fig. 2). Often seen in gazelles and several species of deer, the pronk is an asymmetric running gait during which the lift and footfall of all four feet occurs together. The limbs are often held very stiff during such a movement to propel the animal up into the air. Researchers have yet to come to a consensus regarding a definitive reason for such a

#### Artiodactyla Locomotion,

**Fig. 2** Springbok (*Antidorcas marsupialis*) stotting (pronking) as it propels itself up into the air on all fours

movement, citing everything from play to predator detection in tall grasslands (FitzGibbon and Fanshawe 1988; Hildebrand 1989).

## Limb Loading

Limb loading refers to how an animal distributes weight between limbs to propel itself forward as efficiently as possible. Limb loading of artiodactyls is similar to that of most four-legged mammals. A net accelerating force is produced via the hindlimb as it trails its COM, and the forelimb is utilized for net braking forces, ahead of the COM (Granatosky et al. 2018). In terms of weight support (i.e., vertical forces) the forelimb of artiodactyls bears a greater proportion of body weight than the hindlimb. During the stance phase of slow and fast walking, goats experience a peak vertical force of about 85% of an average goat's weight. Such values could be measured via beam theory of elasticity in reference to the strain experienced by the tibia bone. When jumping, the goat will experience a peak force two to three times that of normal and fast walking. Although transverse forces play a much smaller role in the limb loading pattern of goats, these also significantly increase with jumping as opposed to slow or fast walking (Roszek et al. 1993).

## Gait Kinematics

Artiodactyls have experienced several unique evolutionary changes that impact the kinematics involved with locomotion. The lateral digits have been diminished or have become completely absent, while the medial digits have been elongated. An artiodactyl's foot is referred to as paraxonic, as an axis of symmetry exists between the third and fourth digits. Such changes to the anatomy have allowed for much lighter and longer limbs, ultimately resulting in quicker locomotion with much cheaper energy costs. In most mammals, a joint exists between the tibia and astragalus, with a pulley-shaped surface that articulates with the tibia. Artiodactyls utilize a "double-pulley" astragalus, which significantly increases

free rotation of the foot on the leg in forward-backward motion, with limited lateral rotation of the ankle (Clifford 2010; Theodor 2001).

The metacarpophalangeal (MCP) joint, along with interosseous ligaments of the foot, are significant to force production during artiodactyl locomotion. The MCP joint of artiodactyls is hinge-like and is the only location at which the interosseous ligaments cross. Each digit possesses its own interosseous muscle, which perform flexion at the MCP joints. At slow walking speeds, the MCP joint functions like a spring, and like that of an actuator at higher speed gaits. The interosseous ligaments of the foot allow for force production without the expenditure of metabolic energy. They also play a pivotal role in maintaining the unique "tip-toed posture" of the artiodactyls. Both superficial and deep flexor muscle tendons of the digits, found along the ventral surface of the foot, are important as well. The combination of elongated interosseous ligaments and flexors muscle tendons allows for increased storage of elastic energy, and ultimately more efficient locomotion (Clifford 2010).

Being both the tallest animal on the planet, as well as the heaviest ruminant, giraffes exist as a physical extreme of the artiodactyls. The giraffe's lateral-sequence walking gait is affected significantly by its long neck, limbs, and heavy body weight (Basu et al. 2019). The elbow, knee, and ankle joints all remain flexed during locomotion, although the wrist joint extends to about 10° during the support phase. The giraffe's knee increases in flexion as time passes in both the swing and support phases, which may support the idea that these animals mainly use the knees to walk as opposed to the hip joint. The head and neck, accounting for about 10% of the total body mass, play an interesting role in giraffe locomotion. Stride frequency and oscillation of the neck coincide with one another, as the neck oscillates two times throughout each stride. The neck's horizontal acceleration is opposite that of the trunk, decoupling it from the body's movement. This lessens the horizontal COM forces, which may otherwise impede on the giraffe's gait, and ultimately improves energy expenditure during walking (Basu et al. 2019; Inuzuka 1996; Loscher et al. 2016).

## Vertical Substrate-Use in Goats

In contrast to the more terrestrial lifestyle of most artiodactyls, mountain goats and bighorn sheep frequently traverse dangerous terrains (Fig. 3). Morphologically, these animals tend to have shorter and thicker bones compared to closely related non-alpine species. These osteological modifications allow mountain goats and bighorn sheep to quickly ascend and descend steep inclines without bending or breaking bones. However, the shorter, thicker legs result in higher costs of transport compared to other similar sized ungulates (Dailey and Hobbs 1989).

Beyond vertical rock faces, some goats can traverse up trees. Such movement, also known as arboreal locomotion, requires precision and stability of the limbs, which most mammals do not possess. Compared to a stereotypical rounded foot, the hoof of a mountain goat provides advantages for climbing and slip reduction. Tough keratin lines the toes of these animals allowing for effective uphill walking and a textured pad extending over the nails provides friction and shock absorption when traveling along smooth surfaces. The

interosseous ligaments between the digits also help to maintain stability when traveling on uneven terrain. The mountain goat's hoof provides an increase in lateral stability as well, preventing slippage when traveling downhill. Abad et al. (2016) applied these principles in the development a robotic foot modeled after that of the mountain goat, which required three times the work to induce slippage than a more common rounded foot. As it aids the mountain goat in climbing trees and descending from proximal terrains, it may help humans to do so as well via robotic limbs.

## Migratory Practices

While some artiodactyls, such as the goat, are much more sedentary, other members of the order including the wildebeest, mule deer, and elk may be quite migratory, traveling 50–100 km seasonally. Berg et al. (2019) defined such a concept as partial migration, as artiodactyls consist of both migratory and resident species. Conditions such as weather, seasonal change, predatory density, and access to resources play a pivotal role in determining the manner and tendency in which these species migrate. While some may follow the same migratory patterns yearly, it has been discovered that many subpopulations will migrate across several different varying routes, likely to avoid possible predators or threat of humans (Sawyer et al. 2009). The spring migration of Yellowstone elk may vary based upon how severe and long in duration the prior winter had been. After a heavy winter, the elk may delay spring migrations, but will expedite movements if early vegetation growth is observed (White et al. 2010). In regard to the autumn season, elk migration varies, as Grigg (2007) found that Madison Valley elk would migrate earlier if living within an area of hunting risk during the summer, while those that spent their summers in protected areas would migrate much later for autumn seasons. This is contrasted by the findings made by White et al. (2010), as the Yellowstone population was at no risk of hunting during the summer but migrated much sooner than its Madison Valley counterpart for the autumn season.

**Artiodactyla Locomotion, Fig. 3** Goat are capable of traversing highly variable terrain including (a) trees and (b) steep mountains. The mountain goat's unique hoof characteristics allow for stability and shock absorption while traveling up and down mountain ranges

To help conserve and build energy, the mule deer will utilize stopover sites and movement corridors during migration periods. Foraging and resting occurs at stopover sites, followed by very quick migration to the next stopover site via movement corridors. It is understood that the use of stopover sites and movement corridors allows for energetically efficient migration for artiodactyls (Sawyer et al. 2009).

## Human Interaction

Due to the vast populations of artiodactyls, it is inevitable for interaction with civilization to occur. Unfortunately, many see artiodactyls as disturbances as they may consume and destroy crops, and negatively affect quality of trade such as timber. Of note are wild boar and moose, which browse heavily during the winter, as well as roe deer, which have a significant impact on shrubs within forests. However, via browsing or foraging, these animals help to spread and tread seeds into the terrain. Their droppings help fertilize the soils and encourage growth of forestry (Reimoser and Putman 2011).

Additionally, these animals, in the process of migration, are often involved in road traffic accidents. Artiodactyls, such as the mule deer, have developed migration routes that they follow on a yearly basis. With increasing industrialization, roadways, buildings, and other man-made constructions have impeded on such routes. It is believed that these animals will avoid high-traffic areas as much as possible without heavily affecting their migratory patterns. However, avoiding these areas altogether eventually becomes impossible, and thus, deer–vehicle collisions occur. Along with possible injury and or death via collision, migrating deer that attempt to avoid highways and roads utilize much higher rates of energy expenditure, ultimately decreasing likelihood of survival between seasons. Industrial disturbances not only put the mule deer at risk, but the humans who come in contact with them as well. Due to the strong fidelity migrating artiodactyls have to their migration routes, new construction such as underpasses can play a pivotal role in

decreasing the likelihood of potential collisions and help to maintain the previously discussed movement corridors these animals utilize. Sawyer et al. (2012) found a decrease in deer–vehicle collisions of 81% in a 21 km stretch of US Highway 30 after construction of an underpass. Although other variables will likely need to be taken into account, such as available vegetation, terrain, and other human activity, these changes strongly benefit both migrating artiodactyls and humans themselves (Lendrum et al. 2012; Reimoser and Putman 2011; Sawyer et al. 2012).

## Conclusion

This entry explores the various forms of artiodactyl locomotor behaviors. Extensive research regarding the evolution of these even-toed ungulates has allowed for the understanding of how and why artiodactyls traverse terrains in several different fashions. While the tall and massive giraffe utilizes lateral-sequence lateral-couplet gait to traverse their terrain and survey their surroundings, a pig's short and close to the ground stature requires later-sequence diagonal-couplet gait to maintain stability and avoid body roll. The double-pulley astragalus, as well as the strong MCP joint and interosseous ligaments, allow for highly efficient locomotion. These animals put such traits to use in a variety of ways, as the mountain goat and bighorn sheep traverse up and down dangerous mountainsides and perform arboreal locomotion, while the gazelle leaps on all fours as it prunks to play and/or scout for predators. Spread throughout the world, artiodactyls are found in varying shapes and sizes but all share the distinctive axis of symmetry between the third and fourth digits. Ongoing research will continue to answer questions regarding the vast locomotor practices these even-toed ungulates utilize.

## Artiodactyla Morphology

Skyler Hensarling and Christine Calder  
Mississippi State University, Starkville, MS, USA

## Synonyms

Artiodactyl; Even-toed ungulates; Cloven-hooved

## Introduction

Some of the most well-established terrestrial mammals of the animal kingdom are the ungulates or hoofed mammals. Due to an incomplete fossil record with no readily identifiable intermediates, the precise relationship between modern and early ungulates is currently unknown. Ungulates are primarily divided into one of two orders, Artiodactyla, the even-toed ungulates, or Perissodactyla, the odd-toed ungulates. The primary distinction between these orders involves the morphology of the animals' feet as they deviate from the typical five-digit vertebrate morphology. Artiodactyla is currently considered the fifth largest order of mammals in the world, comprised of 10 families, 8 genera, and 210 species (Etnyre et al. 2011).

## Morphology of Artiodactyl Extremities

As ungulates, artiodactyls typically (with few exceptions) possess digits in which the distalmost phalanx is sheathed in a pointed hoof. They consistently exhibit a paraxonic structure of the foot, indicating that the plane of symmetry of the foot passes between or through the third and fourth digit. In these individuals, the weight of the

animal is supported by the third and fourth digit, while the first digit is always absent, and the second and fifth digits are smaller or completely absent depending on primitivity (Vaughan et al. 2015). Families which possess four functional digits include Hippopotamidae, Tragulidae, Suidae, and the forelimb of Tayassuidae members. These animals typically do not have hooves but a foot with individually spreading digits. Camelidae, Antilocapridae, Giraffidae, and some Bovidae members have only two complete toes with absent lateral digits, while some Bovidae and Cervidae possess two complete toes with reduced lateral digits (Hutchins 2003). In association with weight-bearing on the third and fourth digit, some families, such as Camelidae, Cervidae, Giraffidae, Antilocapridae, and Bovidae, have developed a fusion of the third and fourth metapodials, also known as a cannon bone (Vaughan et al. 2015). It is important to note that the term cannon bone may also be used to describe a single metapodial in Perissodactyls, as opposed to the fused bones noted in several artiodactyl species.

As one of the most expansive orders of living mammals, it is reasonable to consider the broad range of habitats for which individual species within this order are adapted. There are notable variations from this typical artiodactyl morphology noted within included families, such as Camelidae. While dromedary and Bactrian camels exhibit a splaying, partially fused third and fourth metapodial (cannon bone) similar to other artiodactyls, they have simultaneously retrogressed to a digitigrade posture, which is contrasted with the typical unguligrade stance of artiodactyls, in which only the tips of small hooved digits contact the ground during locomotion. This alteration in adaption is presumed to have resulted secondarily from their need to move over soft, sandy ground, as splayed digits prevent sinking. Other animals, such as Caribou or reindeer, maintain an unguligrade stance while developing an increased surface area of the hoof to navigate their natural environment of snow and ice (Vaughan et al. 2015). Solounias and Danowitz (2016) explain that through evaluation of morphological changes observed within a species, particularly in the distal extremities, one can

develop an accurate understanding of habitat preferences as well as phylogenetic history. Because the distal limb is most closely impacted by the environment and variation in substrates, these changes, such as slight alterations in bony anatomy or drastic variation in stance, can provide a multitude of information about that species and its natural and evolutionary history.

Due to the nature of most artiodactyls as prey animals, many possess specialized limbs adapted for speed and running. There are a variety of anatomical changes that are commonly appreciated in animals with this specialization, and many of these are present in artiodactyls of all sizes. A well-appreciated feature of artiodactyls is generalized elongation of the limbs, most particularly of distal segments (with the exception of Suidae and Hippopotamidae). When compared with other species such as canids and other carnivores, artiodactyls have a dramatic elongation of the portion of the limb extending from the carpus distally (Clifford 2010). A tendency for fusion of bones is also noted in several features of artiodactyl morphology. The distal ulna and fibula of the fore and hindlimbs are typically reduced in size or may fuse with the major weight-bearing bones of the limb, the radius, and tibia. In more derived species of artiodactyla, cuboid and navicular bones of the hind limb are also often fused within the foot, resulting in a reduced number of tarsal bones. Many suspect that the tendency for fusion of bones within the distal limbs is a morphologic attempt to lighten the weight of the limb and allow for speed. Members of this order typically also possess a reduction of musculature in the distal limb, replaced by strong tendinous attachments of more proximal musculature. Unlike most land mammals, artiodactyls also do not possess a third trochanter on the lateral femur. Instead, artiodactyls rely on insertion of the superficial gluteal muscles to the proximal tibia after merging with the biceps femoris muscle (Rose 2006). This distal attachment adds to the spring-like motion of the hindlimb experienced during running.

The astragalus, or ankle bone, is the most notable identifier of the artiodactyl hind limb and is the basis of the artiodactyl classification. The astragalus possesses deep grooves at each end to create a

“double pulley” or double trochlea (Hutchins 2003). The depth of these grooves works to maintain motion in the sagittal plane and prevent lateral motion at the site of articulation proximally with the tibia and distally with the navicular and cuboid bones of the hind limb. The astragalus, unfortunately, has also been the source of recent phylogenetic confusion for many during evaluation of the relationship between the orders of Artiodactyla and Cetacea. Molecular evidence suggests that modern ruminants are most closely related to cetaceans, which would indicate that Artiodactyla is not actually a monophyletic order as previously believed. However, cetaceans lack the tarsal structure characteristic of the artiodactyl members, creating discord about the most correct classification of cetaceans from a phylogenetic standpoint (Vrba and Schaller 2000). Thewissen and Madar (1999) suggest that the astragalus that characterizes the artiodactyl tarsus is actually a single morphologic characteristic comprised of multiple individual characters, some of which are actually not completely specific to artiodactyls. It has been shown that cetaceans possess the derived position and shape of the ectal facet (a lateral point of contact with the calcaneus) of the artiodactyl astragalus, which are the most unique characters of the artiodactyl tarsus. This supports a new belief that, despite loss of a characteristic astragalus bone, Cetacea and Artiodactyla may comprise a single order. A merging of these orders would allow reestablishment of a single monophyletic order.

### Evolution of the Gastrointestinal Tract Within Artiodactyla

As previously mentioned, artiodactyls exhibit a wide variety of adaptations among families within the order. With the exception of members of Suidae and Tayassuidae, artiodactyls are obligate herbivores by nature and possess complex gastrointestinal systems specially adapted for this lifestyle. Plant material contains a large amount of cellulose, a complex carbohydrate making up the cellular wall of plant material. A variable amount of protein or other defensive elements may also

be present, depending on the species of plant. Mammals cannot naturally produce enzymes capable of successfully utilizing these compounds as an energy source. Instead, artiodactyl herbivores rely on microbes to more completely extract nutrients from their diet. Gastrointestinal microorganisms provide a way to breakdown complex compounds and produce a more readily useable form of nutrients for the animal. The most derived species have also developed the ability to ruminate to most efficiently maximize nutritional gains. Three suborders are often recognized within Artiodactyla, each with a slightly different gastrointestinal morphology as related to gastric chambers and segmentation. Tylopoda, the camelids, have a three-chambered stomach, which is capable of and relies on rumination. Ruminantia members have a four-chambered stomach, which is also reliant on rumination. Suiformes, on the other hand, have a single stomach that is not capable of rumination. True ruminants of Ruminantia exhibit the most derived gastrointestinal system specialized for a limited herbivorous lifestyle. The rumen, or first chamber of the true ruminant, serves as a fermentation compartment that holds foodstuff after ingestion. Bacteria within the rumen offer a symbiotic relationship for the ruminant, breaking down organic material that others cannot effectively consume. Fermentation inside the rumen releases proteins, carbohydrates, and lipids from ingested material allowing for better absorption of nutrients. Remastication, or cud chewing, occurs through regurgitation of large fibers of plant material into the esophagus and oral cavity for secondary chewing and further breakdown of cellular walls. Following a second swallowing event, food passes into the reticulum, then into the omasum by negative pressure created by omasal wall relaxation, and into the abomasum by muscular contraction. The abomasum serves as the true, glandular stomach of the ruminant. Nitrogen is a natural byproduct of the digestion process of ruminants. Microorganisms within the ruminant gastrointestinal system utilize this nitrogen to make more readily available proteins, which may be then periodically digested by the ruminant as the microbes are mobilized to the intestine

(Hutchins 2003). As prey species, it is particularly beneficial to these animals to have the opportunity to consume a large amount of plant material while having an extended period of time for storage and digestion. This system may, however, become less effective than that of the perissodactyls as food becomes more abundant due to the extended time necessary for passage through the ruminant system. It has been argued that the development of foregut fermentation as exhibited by ruminants led to competitive superiority and rapid successful radiation of artiodactyls as compared to perissodactyls during later Tertiary development. However, Janis et al. (1998), suggest that the two groups are not competitively matched due to the dietary limitations experienced by ruminants. This dynamic is well-demonstrated by radiation of perissodactyls in the late Miocene period in spite of ruminant populations.

### Artiodactyla Skull Morphology

Further adaptations to a primarily herbivorous lifestyle are reflected through skull morphology of the artiodactyls. The antorbital (in front of the eye) portion of the skull is generally elongated and the skull has an overall flat profile dorsally. This silhouette may be interrupted by dorsal extension of a complete or mostly complete orbit. Almost all members of Artiodactyla possess some form of protrusion from the dorsal skull such as in the form of keratin sheathed horns of bovids, bony antlers of deer, or epidermis-covered ossicones of giraffes. Typically, these extensions have a protective function and are characteristically larger in males than females. Caudally, the artiodactyl mastoid process of the petrous temporal bone is exposed between the squamous and exoccipital bones. Most Suidae members are the exception in that their squamosal bone often conceals the mastoid process. Furthermore, suids tend to exhibit dentition separate from other artiodactyls, such as camelids and bovids. It has been recognized that suids tend to have a more diverse omnivorous diet compared to the many ruminants included in Artiodactyla. As such, suids tend to have teeth with a low crown and bunodont

(cusped) cheek teeth. Ruminants and camelids tend to exhibit classic hypsodont (high-crowned), selenodont (high-ridged) cheek teeth typical for herbivorous animals. Camelids and more derived ruminants also have no upper incisor teeth, while primitive species typically possess three incisors in each upper quadrant. Primitive species generally also possess canines that may project from the mouth or are at least well-developed. A space is almost always present between the canine and first premolar of the lower jaw (Rose 2006).

### Sexual Maturity and Reproduction

Sexual maturity of the artiodactyl is most commonly reached at approximately 18 months of age, and the females typically birth their first offspring at around 2 years of age. Delayed sexual maturity as well as increased birth weight, increased adult size, and dominance can help adult females to more effectively access resources for their young, which can lead to longer reproductive success. With this change in development, a decrease in sexual dimorphism in size and protective characteristics (such as horns) among bovids is also typically observed (Vrba and Schaller 2000). Gestation is variable between species, lasting anywhere from 5 to 11 months. Female artiodactyls possess either two or four teats with the exception of Suidae members. Suids typically possess between 6 and 12 teats as made necessary by their generally larger litters (Hutchins 2003).

### Coat and Coloration of Artiodactyls

While coloration patterns are typically species specific, artiodactyls generally possess a double fur coat. The outer coat is long, coarse, and functions to protect against various elements of the weather. A second undercoat of short, fine hairs assist in temperature control. Some domesticated species have been selectively bred to alter this natural coat and select for particular characteristics, such as sheet and their wool. Variations in coloration can be linked to basic evolutionary

pressures to effectively conceal and communicate. White or dark markings on the faces and rumps of social ungulates are particularly closely associated with their diurnal (day dwelling) nature. These markings may play a part in marking an individual as having a role or place within a social grouping, signaling of a mother to her young, or communication of aggression or other intraspecific communication (Caro 2005). Communication is also accomplished through the use of epithelial scent glands, most commonly located on the tarsi, between the hooves, or on their faces. These glands are typically paired and secrete specific chemicals that may be physically transferred by rubbing or nuzzling or aerosolized. In addition to communication of location or territory, these glands, their secretions, and urine may be used to self-mark, communicate threats, or as a physiological state identifier (Hutchins 2003).

## Conclusion

Artiodactyla is one of the broadest, most well-represented orders of animals alive today. Comprised by over 200 species of animals representing a wide variety of habitats, Artiodactyla is one of the most evolutionarily successful living orders. Despite what is known about this large order, there are several unknown factors associated with the evolution of these species and their relationship with other living orders at this time. However, the examination of artiodactyl morphology and their natural history yields a quantity of information that can be used to examine the phylogenetic development of the largest land mammals alive today and their association with several species around the world.

## Definition

Characteristic movements and behaviors exhibited by members of the mammalian

taxonomic order Artiodactyla that best meet their survival and fitness needs.

## Introduction

Even-toed ungulates, classified in the diverse order Artiodactyla, traverse landscapes in their home ranges and migration routes in ways that best serve their needs to survive and reproduce. According to the IUCN Red List, there are 10 families within Artiodactyla (e.g., Bovidae, Cervidae, Giraffidae, Suidae, and others) including the recent consolidation with the 13 families of order Cetacea (i.e., Balaenopteridae, Delphinidae, Phocoenidae, etc.) to form the proposed monophyletic order Cetartiodactyla (International Union for the Conservation of Nature, [n.d.](#)). This group of marine mammals has been shown to display the closest genetic relatedness to artiodactyls compared to any other taxon through anatomical studies of paleontological and modern specimens, genetic evaluations of loci isolation, short interspersed elements (SINEs), and other molecular characteristics (Shimamura et al. [1997](#); Nikaido et al. [1999](#); Price et al. [2005](#)). Though acknowledging the current classification, this chapter will focus only on the representatives within terrestrial Artiodactyla as it pertains to generalized concepts of spatiotemporal movements.

Though their movements are influenced by numerous limiting factors, members of this order have adapted behavioral and morphological characteristics that have enabled them to mitigate the risks of navigation and be one of the most diverse and successful mammalian orders in the evolutionary arms race. Evolution of physiological and behavioral mechanisms to support artiodactyl movement have developed as results of respective climates and landscapes of species occurrence and are subject to continued changes in response to climate variability, anthropogenic influences, and other environmental factors (Post and Stenseth [1999](#)). Examples include but are not limited to dentition for morphological suitability to preferred forage strategy (Mendoza and Palmqvist [2008](#); Janis and Ehrhardt [1988](#)), hoof shape and pad traction to traverse rugged terrain (Rui et al.

[2017](#)), unguligrade foot posture, cannon bone formation (Clifford [2010](#)), various social habits (Geist [1974](#)), and specialized fat deposition and water conservation in extremely arid environments (Nelson et al. [2015](#); Cain et al. [2010](#)).

An example of behavioral adaptations includes species specialization to specific landscapes and temperature response. A study by Street et al. ([2015](#)) showed through statistical analysis of geographic movement data in association with landscape characteristic records that the strictly cold climate-adapted moose (*Alces alces*) occurring in Ontario, Canada, selected habitat based on the thermal characteristics of different stands over optimal forage capabilities. This is believed to be an effort to avoid heat exhaustion, with strong preference for well-shaded timber stands, aquatic environments, marshes, and other areas during the summer months capable of sustaining temperatures below 27 °C (Franzmann [2000](#)). Though this lends itself to optimal thermoregulation capabilities, it can be a limiting factor to overall health of individuals as these areas could potentially be sub-optimal for nutrition and reproduction. Continued observation and management for optimal cover and forage will be necessary as average global temperatures continue to increase.

## Herding Behavior

From massive herds to solitary nomads, artiodactyls exhibit various degrees of aggregation behavior dependent on factors such as species, age, sex, forage availability, spatial scales, and predator presence (Geist [1974](#)). The primary reasons for herding are thought to be based on the ability to quickly gather and communicate information for threat awareness and, to a lesser extent, resource discovery. Individuals in larger herds have lower mortality potentially due to more members present to detect danger, while members of smaller groups exhibit higher chances of being singled out by predators (Kie [1999](#); King et al. [2012](#)). Although herding is beneficial to species persistence, individuals can experience trade-offs with life in a group. The “selfish herd” theory delves into what is, perhaps, the most significant trade-

off as it pertains to predation. Though membership protection is heavily dependent on each animal, individuals may indirectly vie for the centermost position within the group using mostly random movements. This space is believed to be the area of maximum value within the herd and also serves as the area of least mortality risk; however, mortality risk is influenced greatly by group density and position. As the distance from this area increases, so do the odds of mortality. During an encounter with a predator, individuals may attempt maneuvers to gain maximum protection from the threat. Though animals on the periphery of the group are typically the ones at greatest risk of mortality, the complicated motions of individuals can confuse predators, and targeting of prey can become difficult (Breed and Moore 2016). Although there are instances in which animals, such as maternal or dominant individuals, will serve as defensive sentinels, it can be interpreted from selfish herd theory that the subordinate herd members are often the ones that are excluded from the center via competition and are the most exposed, while more dominant individuals take up the center position and make no attempt to hinder the predator's efforts (Morrell et al. 2011). However, caution should be exercised as this theory can lead to potential misinterpretation of natural selection. The oftentimes randomness of herd movement and likelihood for any herd member to face predation, regardless of social ranking, may introduce too much variance to assume that a population's genes and fitness are significantly correlated with geographic location within herd movements.

King et al. (2012) tested the selfish herd hypothesis with captive sheep (*Ovis aries*) ( $n = 46$ ) and a herding dog (*Canis lupus familiaris*) outfitted with GPS equipment to record individual locations every second to determine if the sheep were indeed making a calculated effort to position themselves in the centermost area of the fleeing herd. Their analytical models showed "classic aggregation and avoidance behavior" whereby sheep seemed to be attracted to what they cognitively approximated as the centermost location of the herd; however, the sheep did not appear to be calculating the position

of fellow herd mates relative to their position in the herd. They did note that various herd sizes, more precise individual movements relative to conspecifics, and other danger types should be subject to further selfish herd research.

Other plausible explanatory mechanisms for herding behavior include animals in herds having the opportunity to observe resource location behaviors of other herd members as well as opportunities to learn travel routes as they move across space. By using their senses, individuals can cue into movements of others around them and exploit resources discovered by other individuals to reduce energetic costs and risks of predation. Though this proves valuable for success of the herd, intraspecific competition will begin to occur within the group as discrete resources are discovered and used. This can become another trade-off of herding behavior as it is very difficult for an animal in a social unit to exclude others from resources (Breed and Moore 2016).

Sexual segregation and group size vary with season and species. During the nutritionally taxing parturition and nursing period for females, various species will exhibit moderate to high levels gregarious behavior (e.g., wildebeest, *Connochaetes* spp.), whereas others may remain relatively solitary (e.g., white-tailed deer, *Odocoileus virginianus*) during lactation and the critical stages of their young's development (Estes 1976; Bertrand et al. 1996). These behavioral differences in female representatives of species vary with taxonomic classifications, carnivore presence, and food and cover availability. Bertrand et al. (1996) stated that female white-tailed deer vigorously defended selected parturition areas from related and unrelated conspecifics leading up to and after birth of their fawns. Optimal areas, defined as areas with most available food resources and cover, seemed to be occupied by the most dominant individuals, whereas occupancy of less optimal areas seemed to descend with subordinate social levels. During the non-breeding season, however, white-tailed deer bucks are commonly known to aggregate together in what are known as "bachelor herds." These groups typically disband as the rut initiates and intraspecific competition between bucks

intensifies (Breed and Moore 2016). Though bachelor herd formation isn't exclusive to white-tailed deer or even Artiodactyla itself, it is represented well throughout the order.

Caribou (*Rangifer tarandus*) cows utilize mutual group vigilance and will rarely exclude conspecifics from parturition sites to the levels seen in white-tailed deer. However, caribou live in far northern latitudes and are considered constant migrants such that they are always on the move between summer and winter ranges and are frequently in closer proximity to conspecifics throughout the year. In contrast, white-tailed deer hinds appear to distribute themselves over more defined home ranges, with far-ranging movement behavior linked mostly to male dispersal (DeMars et al. 2013; Frame et al. 2008; Tierson et al. 1985).

Estes (1976) described wildebeest parturition as "mobile," considering the species is highly gregarious and targeted extensively by predators such as spotted hyena (*Crocuta crocuta*). Because of this, wildebeest seem to tolerate conspecifics more so than other members of Artiodactyla during parturition and take advantage of a concept known as "predator swamping." Predator swamping is defined as birth synchrony within a population that results in a "flood" of offspring which cannot be consumed by potential predators due to an influx of vulnerable prey in a very short time frame. Although this strategy is not exclusive to wildebeest, Estes mentions they seem to be a rare example in how this strategy is utilized. Offspring are fully mobile within hours after birth and accompany the mother and conspecifics immediately after they are capable of travel. This further combats predation in that there are too many mobile, young targets than what can be actually eaten. This differs from many other members of Artiodactyla in that most species isolate their offspring for various amounts of time to prevent harm coming to them by means of predation or from conspecifics themselves. Estes does make a point to mention that offspring mortality values were found to increase with decreasing herd and calf density, and found offspring in larger aggregations were not as subject to predation even when parturitions were out of synch. These

studies of artiodactyls highlight that species in this order have adapted varying parturition strategies based on movement patterns to maximize survival and fitness.

## Migration

Migration behavior is exhibited across numerous taxa and is utilized for a range of reasons, including reproduction and predation avoidance. The main driving factor, as it specifically pertains to artiodactyls, seems to be that even-toed ungulates adjust their movement patterns with the growth of new, high-quality vegetation throughout the annual cycle in order to maintain or increase fitness (Chynoweth et al. 2015; Jesmer et al. 2018; Skarin et al. 2010). The new vegetation growth is driven by weather patterns, thus affecting the scale at which animals will travel (Holdo et al. 2009). It is widely recognized that animals will travel longitudinally, from one range to another. But altitudinal migrations, between lower and higher elevations, are also prevalent especially among montane species, though these areas do not always correlate with increased foraging. Higher altitudes have been associated with predator avoidance and biting insect relief. Factors influencing altitudinal migrations include vegetation configuration, topography, landscape ruggedness, and even human activity (Skarin et al. 2010). Although not readily distinguished by observation of animal behavior alone, cues to migrate include day length, weather pattern changes, feeding changes, predator, and insect harassment. The various learned and specific physiological behaviors that react to these phenomena are what give rise to migration (Jesmer et al. 2018). Once movement has initiated, ungulates have traditionally been thought to utilize navigational methods such as following unique landscape formations, paths, and social information from experienced conspecifics. It should be noted that any movements, regardless of scale, are heavily dependent on environmental influences occurring at the time of action. This causes variation in action outcomes such as

destination, travel speed, arrival times, time spent there, or if a migration occurs at all (Winkler et al. 2014).

Jesmer et al. (2018) tracked movements of resident and translocated bighorn sheep (*Ovis canadensis*) and moose to demonstrate that ungulate migratory strategies may be rooted in learning from more experienced conspecifics. In what has been called “green-wave surfing,” a population of animals that has resided in a region for generations have been shown to follow the emergence of new vegetation by migration. These groups are called a historical population (>200 years residency), and these animals are often traveling extended longitudinal or altitudinal distances as they follow their food source. Because these movement patterns remained unbroken for an unknown amount of time, the researchers sought to answer the question if these migration routes are innate behaviors or learned from conspecifics in a process dubbed “cultural transmission.” By translocating and tracking individual bighorn sheep and moose to novel landscapes, they were able to assess if migration routes were born from inherited migratory paths (i.e., genetically heritable migratory pathways) or a product of cultural transmission in unfamiliar landscapes. After the translocations, they used data from GPS collars to measure where translocated and non-translocated animals were spending their time on a seasonal basis. They further calculated time spent in areas corresponding to the magnitude of vegetation emergence of occupied landscapes. Their findings showed a dramatic difference in translocated and historic population movements. Historic populations typically maintained their migration patterns, with 65–100% of study subjects exhibiting migratory behavior. Translocated herds remained relatively confined to the regions of their release until enough generations had passed to allow the descendants of translocated animals to gradually adapt to the movements and green-wave surfing culture of the native population over time. Only 9% of these translocated animals exhibited migration behavior. Surfing knowledge among native populations was roughly twice that of translocated animals which suggests that knowledge of local green waves

builds with experience and may be culturally handed down over generations. As this knowledge increased, the migratory propensities followed.

## Home Range Movement

An animal’s home range is the space it utilizes to carry out the majority of its life history. The spatial and temporal scale at which these spaces are utilized depends greatly on availability of resources and environmental characteristics and is often driven by seasonal weather patterns, landscape configuration, forage availability, cover, competition, population density, predator presence, habitat fragmentation, and anthropogenic land use (Gingery et al. 2017; Powell and Mitchell 2012; Wattles and DeStefano 2013). Artiodactyls often exhibit behavior conducive to the utilization of roughly defined spaces quite dynamic in scale and temporal occupation. Home ranges can span from several square meters to many square kilometers and may be utilized within a single season, across seasons, or for the duration of an entire life span dependent on species life history requirements (Börger et al. 2008). Spatiotemporal dynamics of species are influenced by the current environmental state and needs of the individual animal itself, meaning that an animal will adjust the scale of use of its home range dependent on the quantity and quality of resources, landscape configuration, and its own body condition (Bevanda et al. 2015). Home range use can further vary based on age, sex, and group size and comes with its own range of associated risks (Fennessy 2009; Marino and Baldi 2014). Duquette et al. (2015) found that female white-tailed deer in a landscape inhabited by multiple predator species adapted their movement based on areas of nutritional value and risk potential. Predators were shown to occupy areas with greater optimal forage potential value for deer, thus making these areas beneficial yet also risky, especially during seasons of neonate dependence. By monitoring telemetry data, the deer were observed interchanging their movement habits between resource-rich areas with greater direct mortality risk by gray wolves

(*Canis lupus*) and sub-optimal resource areas with reduced risk of direct mortality from predation. However, the trade-off for this movement pattern was that subsequent neonates were more exposed to predation from carnivores such as coyotes (*Canis latrans*). Movements were also shown to be plastic, or flexible, whereby if an individual's fawn was depredated, hinds would respond with a more conservative foraging strategy to reduce energy expenditure and risk of predation. Fawns from subsequent reproductive attempts were therefore more likely to have greater survival as a result of plasticity in their parent's foraging strategies.

Movement ecology, as related to an animal's resource use within its home range, is an ever-evolving field of study, and the development of new methods are necessary to continue advances in ecological research. New technological, statistical, and computational advancements are developed frequently and can advance our understanding of spatiotemporal dynamics in many species, particularly those that are difficult to observe or transient in nature (Allan et al. 2018; Hebblewhite and Haydon 2010; Millspaugh and Marzluff 2001). Common methods of spatiotemporal and movement research in artiodactyls involve telemetry monitoring by means of VHF (very high frequency) and GPS (Global Positioning System) collars. These kinds of devices and their various applications have revolutionized the study of animal movements across space (Cagnacci et al. 2010; Hebblewhite and Haydon 2010).

Rivrud et al. (2010) used GPS data to determine if red deer (*Cervus elaphus*) home range use fluctuated as a consequence of seasonal climate variables. They suggested climate changes could directly influence animal activity patterns within their home range if it impacted resources necessary for survival and fitness over time. They developed two temporal hypotheses related to season-specific variation and potential climate change effects on red deer home ranges. First they hypothesized short-scale effects of climate change as it related to daily and weekly weather events (e.g., temperature, precipitation). They further hypothesized there would be longer-term

effects at bimonthly and monthly time scales during the summer season related to vegetation growth. They collected hourly GPS collar locations from 47 red deer hinds as well as weather (i.e., temperature, precipitation, snow depth), habitat, and forage productivity covariates.

Their results correlated with their hypotheses in that animal activity seemed to be greatly influenced by different weather patterns. Home range size increased during times of abnormal winter warmth, whereas the opposite was seen during cooler summer temperatures. It is believed that the positive relationships between home range sizes and temperature are that deer respond to times of more extreme than average seasonal temperature by limiting their space use in order to conserve energy. When temperatures abnormally fluctuate in relation to normal parameters, such as higher than normal winter temperatures, deer will expand space and resource use to take advantage of thermal changes. It was noted that similar findings have been reported with cervid research, such as by Hayes and Krausman (1993). Changes in home range size as related to precipitation were different from temperature with season and scale. Positive relationships were maintained between home range size and periods of longer precipitation but contained no obvious seasonal influences. However, shorter periods of precipitation saw seasonal influence on home range size as shortened precipitation in winter maintained a positive and shortened precipitation in summer maintained a negative relationship with home range. Using the kernel method, a 10 mm increase in precipitation was projected to correlate with a 90% home range size increase. Rivrud et al. (2010) suggested that this seasonal variation in home range size resulting from shortened periods of precipitation may be related to search and utilization time for shelter by red deer, particularly in sub-optimal habitat, as precipitation can be thermally expensive to ungulates (Parker 1988). But this explanation did not correlate well with longer periods of precipitation, and further research would be needed to determine possible correlations.

Snow depth was also shown to exhibit influence on home range size – as depth increased home range size tended to decrease. Yet it was

predicted that home range size dramatically increased with a 10 cm reduction in snow depth. Home range retraction during heavy snow events could be due to reduced levels to conserve energy considering that movements in heavy snow are energetically costly (Parker et al. 1984).

Home ranges also varied in size in relation to quality of habitat in red deer, specifically in short temporal scales. In areas where forage and cover were lacking, home range sizes were larger than areas with optimal resources, but extent of home range varied with surrounding landscape characteristics (e.g., forest vs. pasture lands). This could be in response to lower densities of resources in sub-optimal areas, resulting in resident deer needing to utilize larger spatial extent to meet metabolic demands and other life history needs.

## Conclusion

Ungulate movements, particularly migrations, are recognized as one of nature's most awe-inspiring phenomena. Much scientific knowledge pertaining to mammal movements stems from migration of these charismatic fauna, such as the caribou of the arctic and the wildebeest of the Serengeti. Other findings are being published on lesser known migratory movements such as those of mule deer (*Odocoileus hemionus*) and pronghorn (*Antilocapra americana*) in western North America (Sawyer et al. 2005; Lendrum et al. 2013). Anthropogenic barriers and bottlenecks (i.e., fences, extensive energy development, roads) are increasing limitations to migration paths in artiodactyls worldwide, often times completely cutting off historic routes. This poses direct survival implications for ungulates as well as human cultures dependent on these species. Depending on geographic location, ungulates must traverse rivers, rugged topography, interpret homogenous landscapes, and avoid predators. But as global climate patterns shift, vegetation growth may change spatially and temporally which could also skew migration cues and navigation. This may impact timing and magnitude of migration and may result in movements that are asynchronous with resource availability. Further research

of spatiotemporal movement is needed in the hope that these efforts to understand and preserve ungulate movements will facilitate sustainability of populations. Proper management strategies as well as new management or protection ideas for areas known to be important migration corridors, high-quality habitat, or harbor high population abundances could offer some solution to preserve these behaviors in the future (Berger 2004).

## Asexual Reproduction

Jared Edge  
Oakland University, Rochester, MI, USA

## Synonyms

Agamogenesis; Parthenogenesis

## Definition

Reproduction without the sexual union of male and female gametes.

## Introduction

Asexual reproduction is any form of reproduction in which a single parent organism produces offspring without combining male and female gametes. The produced offspring are either identical clones of the parent organism or are genetically similar with no additional genetic material being added. Any differences between the parent and offspring organisms that do arise are typically due to mutations or genetic recombination when undergoing meiosis. However, most forms of asexual reproduction do not make use of meiosis or the fertilization that occurs during sexual reproduction.

Asexual reproduction is primarily observed in single-celled prokaryotes, such as bacteria, as this is their primary form of reproduction. Prokaryotes are capable of transferring genes between

individuals, similar to sexual reproduction (Narra and Ochman 2006), but any new offspring are spawned asexually. Although it is rarely used as a primary form of reproduction, many species of plants, fungi, and animals are capable of reproducing asexually. By reproducing asexually, an individual can generate a high number of offspring, but each of these offspring will be genetically similar to the parent. This form of reproduction can produce short-term rapid population growth but can also limit the genetic diversity of a species.

## Binary Fission

The term asexual reproduction refers to a wide range of reproductive behaviors, including binary fission. Binary fission, also known as cellular cloning, occurs when a parent organism copies its genetic material and splits into two identical daughter organisms. This process is the primary form of reproduction used by prokaryotic organisms such as bacteria. Binary fission is similar to mitosis, which is performed by eukaryotic cells, except for the absence of a true nucleus in prokaryotes. Although eukaryotic cells divide through mitosis or meiosis, some organelles, including mitochondria and chloroplasts, divide via binary fission.

Binary fission can be classified as one of four types depending on where the division occurs. Simple binary fission can occur along any plane in the organism. Transverse binary fission occurs along an organism's transverse axis, the horizontal line that runs across the organism. Longitudinal binary fission occurs along an organism's longitudinal axis, the vertical line that runs lengthwise along an organism. During oblique binary fission, the division occurs along a slanted plane. This form of binary fission can result in daughter organisms that are unequal in size (Biology Dictionary [n.d.](#)).

Although the most common form of fission results in two organisms, multiple fission, where a parent organism splits into more than two daughter organisms, does occur in some species of protists, protozoans, and slime molds (Britannica Education Publishing 2011). During

this process, multiple copies of the parent organisms' nuclei are made before splitting into individual cells. In most forms of multiple fission, the additional nuclei are stored in the central cavity before forming daughter organisms. Some organisms, such as the marine alga *Acetabularia*, instead form compound nuclei with all of the copies stored with the parent nuclei. During this process, the nuclei separate right before gamete formation (Bonner 1998).

## Budding

Budding is another form of asexual reproduction that involves a parent organism splitting into a mother and daughter organism. During this process, a "bud" grows from the parent organism and splits after reaching full maturity, becoming a daughter organism. Some single-celled organisms, such as yeast, reproduce through budding, but this process is much more prolific in plants and some aquatic animals, including corals and sponges. Some parasites use an internal form of budding in which the daughter organism grows inside of the parent organism and is expelled upon reaching maturity (Smyth and Wakelin 1994).

During the budding process, the new cell starts to form as a bubble on the side of the parent organism and fills with cytoplasm until it is the same size as the parent organism. At this point, the nucleus divides, with one copy moving into the new cell. Following this, the daughter organism separates from the parent organism, forming a new cell. In some species, the budding process can occur at any location along the organism, but other species have specialized areas that budding is restricted to. Although daughter organisms typically separate from the parent organism once the budding process has concluded, some species do not separate and instead form colonies (Encyclopedia Britannica 1998).

## Vegetative Reproduction

Vegetative reproduction occurs when a fragment of a parent plant grows into a new plant. This process uses vegetative parts of the plant, such

as the leaves, roots or stem to produce new plants. New plants can also be formed from a specialized reproductive structure, such as a runner, rhizome, tuber, corm, or bulb. Many plants can reproduce through vegetative reproduction, with upwards of 70% of all plants being capable of this form of reproduction (Klimés et al. 1997). However, this process is rarely used exclusively as it can reduce genetic diversity.

Vegetative reproduction can be artificially induced and is used by many horticulturalists to replicate plants (Swingle 1940). When used this way, a superior plant can be reproduced endlessly and at a much faster rate than through seed propagation. Artificial vegetative reproduction can be performed by using apomictic seeds (seeds produced asexually), specialized vegetative structures, layering and cutting, grafting and budding, and tissue cultures (Perrott et al. 1998). Layering and cutting induces a plant to regenerate a lost limb; layering occurs when the lost limb is still attached, and cutting occurs when the limb is detached. Grafting and budding are the most widely used methods of propagation and involve joining multiple plant parts together using tissue regeneration. When the plant part being added is a bud, the process is called budding. Tissue cultures provide embryos and shoot tips with artificial nutrients and other inorganic elements to encourage growth.

## Sporogenesis

Sporogenesis is the production of reproductive cells, called spores, which are used by plants, fungi, and algae. Many of these spores are produced asexually but require fertilization after being dispersed to grow into a new organism. Fungi and some species of algae are capable of true asexual reproduction by producing spores that do not require fertilization before growing into a new organism (Raven et al. 2005). Fungi use a variety of methods to produce spores from mother cells that are then dispersed near the parent or ejected to be spread by wind, water, or other organisms. After landing, the spores will then wait to germinate until the environmental conditions are optimal for growth. Although fungi are

capable of reproducing asexually using a variety of methods, the creation of spores is the most commonly used.

## Fragmentation

Fragmentation occurs when an organism grows from a piece of the parent organism that was severed. This process can occur as a result of outside forces or be initiated by the parent organism. In order to reproduce using this method, organisms need to develop specialized organs or even regions of their body that can be removed without disrupting the rest of the organism. Additionally, these sections would need to be able to regenerate to form a brand new organism. Fragmentation is similar to regeneration, except that each piece has the possibility to form a new organism.

Fragmentation is used by many molds, plants, lichens, and some animals such as echinoderms and annelid worms. When performed by plants, fragmentation is a common type of vegetative reproduction. Many lichens, a symbiotic union of photosynthetic algae/bacteria and fungi, reproduce through fragmentation so that the new growths possess both of the symbionts. Some organisms reproduce through clonal fragmentation in which the parent organism splits into several fragments, each of which is capable of growing into new organisms. This form of fragmentation is used by echinoderms, such as sea stars, and is also referred to as fission. The survivability of the produced fragments is size-dependent, with the larger fragments being much more likely to grow into a new individual.

## Agamogenesis

Agamogenesis is any form of reproduction that does not involve fertilization by a male gamete. Many organisms that normally reproduce sexually are also capable of reproducing asexually through one of several processes. Parthenogenesis, also known as unisexual reproduction, occurs when an unfertilized female (rarely male) gamete grows into a new individual. Parthenogenesis

occurs in a wide variety of plants and invertebrates and is the most common form of asexual reproduction in vertebrates. Some species reproduce through parthenogenesis when there are no fertile males present or environmental conditions are not conducive to raising offspring; other species, such as the New Mexico whiptail lizard, reproduce exclusively through parthenogenesis as there are no males of the species.

The gametes that undergo parthenogenesis can be either diploid (two sets of chromosomes) or haploid (one set of chromosomes). Haploid parthenogenesis occurs in some plants and bees. During this process, a haploid gamete grows to become a haploid adult. In bumble bees (*Bombus terrestris*), haploid individuals can differ in size and reproductive success from diploid adults, with haploid males being larger and less reproductively successful than the diploid males (Duchateau and Mariën 1995). Diploid parthenogenesis is a much more common process where a haploid gamete either duplicates its chromosomes or fuses with another haploid gamete before developing into a diploid adult. Unlike other forms of asexual reproduction, these individuals are not true clones of the parent organism as the meiotic process alters the genetic material.

Although less common, apomixis is another form of agamogenesis. Apomixis occurs in sexually reproducing plants when no male gametes are available. This process involves a plant producing spores that do not require fertilization to grow into an identical offspring. Apomixis is widely used in ferns and in flowering plants but is rare in other seed plants (Wang and Tseng 2014). There are two kinds of apomixis. Gametophytic apomixis occurs when an embryo forms from an unfertilized egg that did not complete meiosis, instead undergoing a process similar to mitosis. Nuclear embryony is another form of apomixis in which an organism creates an embryo without the use of reproductive cells, instead drawing the necessary materials from other tissues. This particular reproductive method is primarily performed by citrus fruits when male gametes are not readily available. Although much rarer, male apomixis can occur with reproductive materials being derived entirely from pollen.

## Advantages

Asexual reproduction can provide many short-term benefits by allowing an organism to reproduce rapidly without having to find a viable mate. By not requiring a conspecific to reproduce, all members of a population can produce offspring, effectively doubling the rate of potential growth compared to sexually reproducing populations. This effect is known as the twofold cost of sex. By rapidly reproducing, a species can attempt to overwhelm potential competitors through sheer force of numbers. This rapid reproduction can also prevent invaders from gaining a foothold by quickly occupying a niche.

Without the need for a viable mate, asexually reproducing organisms can reproduce at any time with the requisite amount of resources and do not need to expend any extra resources or time on mating routines or to raise offspring as most asexually produced children are independent from birth. By reproducing asexually, an organism can choose when and where to reproduce and will continue to do so until conditions are no longer favorable. Without any investment from the parents, offspring are generally fully matured when born or, in multi-celled organisms, can mature faster than sexually reproduced organisms, with crops that are produced asexually reaching maturity much faster than those that are produced sexually as they do not have to grow from a seed.

This form of reproduction is especially useful for species that live in regions with low population density or few resources as many types of asexual reproduction simply split new organisms from the parent. Many species that maintain the ability to reproduce asexually do so for emergency situations when there are no viable mates or some other aspect of the environment prevents sexual reproduction from being a viable option. Asexually reproducing species can thrive in the climate that they have adapted to, including extremely hostile environments. However, these adaptations are typically very rigid, so that any changes in the environment can devastate a population that is not already equipped to deal with the new surroundings.

## Disadvantages

Conversely, asexual reproduction has a major drawback: a lack of genetic diversity. Barring potential mutations, most forms of asexual reproduction create exact replicas of the parent organism, which means that any new organisms are susceptible to the same diseases and other environmental dangers that the parent organism is vulnerable to. If a population of organisms share vulnerability to the same dangers, then a mass extinction event can occur, wiping out that population. A mass extinction event can occur even in a population that reproduces sexually, but asexual populations are much more susceptible (Wills 2003). Although a lack of genetic diversity is a concern for asexually reproducing species, many bacteria offset this cost by having a high rate of mutations, allowing for enough genetic diversity to protect a population (Suomalainen et al. 1987).

A high rate of mutations can improve species fitness over time, but it can also lead to a high number of mutations with deleterious effects. Mutations with strongly deleterious effects will quickly be removed from the gene pool through natural selection. Mutations with only mild deleterious effects can persist in a population and increase the mutation load and possibly reduce that population's fitness. Compared to sexually reproducing populations, species that primarily reproduce asexually tend to have a higher mutation load, lower fitness, and more deleterious mutations (Kondrashov 1982).

## Alternating Use

Many multi-celled species that are capable of asexual reproduction also engage in sexual reproduction to avoid the disadvantages. The ability to alternate between asexual and sexual reproduction is termed heterogamy. By switching between these two methods of reproduction, an organism can maintain a sufficient level of genetic diversity while capitalizing on the speed and efficiency of asexual reproduction. Some animal species, such as the crustacean *Daphnia*, rapidly reproduce asexually in the spring and then switch to sexual

reproductive strategies when competition starts to increase.

Bengtsson (2003) examined how often a primarily asexual population would need to engage in sexual reproduction to maintain similar levels of genetic diversity as sexually reproducing populations using genetic models. In order to maintain a comparable level of genetic diversity, an asexual population would only need to produce a few sexual individuals per generation. This method can allow for a great degree of genetic variation that can be easily compared to that in sexual populations. As the number of sexual events required to maintain a sufficient amount of genetic diversity is very low, this strategy may help explain some species that have only been observed reproducing asexually while also having a high degree of diversity (Jonsson et al. 1996).

## Conclusion

Asexual reproduction covers a wide range of behaviors that are employed by many different organisms, all of which are defined by the lack of fertilization that characterizes sexual reproduction. These behaviors can allow a species to quickly reproduce with fewer resources and investment than is required by sexual reproduction but comes at the cost of reduced genetic diversity, which can endanger a population. To counter this disadvantage, many single-celled organisms have a high mutation rate, and many multi-celled organisms use a combination of sexual and asexual reproduction depending on the environment.

## Assemblage

Yvan I. Russell

Middlesex University, London, UK

## Synonyms

Aggregation; Collection; Organization; Set; Structure

## Introduction

In nature, assemblages are everywhere: a blade of grass is an assemblage of plant cells and pores; a beehive is an assemblage of bees and beeswax; a jungle is an assemblage of animals, plants, and microorganisms. Philosophers (e.g., DeLanda 2016) define “assemblage” as a collection of heterogeneous elements located within some area of interest. An example of an assemblage might be a study area within a rainforest. Assemblages have the following features (DeLanda 2016): they have a boundary (e.g., a defined study area), they have constituent parts which occur together non-randomly (e.g., animals in the study area), the elements inside are interrelated to some extent (e.g., a rainforest ecosystem), the constituent parts might be removable (e.g., animals can depart the area; trees can be cut down) while keeping the identity of the assemblage intact (e.g., a rainforest can still be called a rainforest, if not too many elements are removed). Assemblage is a fundamental principle of “social groups” as they occur in the major transitions in evolution (Bourke 2011). However, the word “assemblage” itself has an even broader definition, applicable even to collections of highly dissimilar objects (DeLanda 2016), such as the assemblage of people, books, bricks, windows, laboratories, and buildings that make up a university campus. The way that a scientist defines an assemblage depends very much on the scientist’s goals. Assemblage is not necessarily a spatial concept (DeLanda 2016) – but in studies of animal behavior and cognition, studies of assemblages are

sometimes tied to geographic locations. Here, the focus is on two main topics: (1) comparison of different species living in the same area using a single type of test, and (2) archaeological and fossil assemblages. Examples of such studies are given below.

## Comparative Studies

In the comparative study of living animals, an assemblage is a way to organize a cross-species comparison. For example, Nevitt, Reid, and Trathan (2004) investigated the foraging cognition of an assemblage of Antarctic seabirds (petrels, albatrosses, shearwaters) focusing on the way that each species of bird uses its olfactory capabilities to detect krill (a crustacean which is a primary food source in the Antarctic Ocean). They artificially simulated the scent of krill, using vegetable oil slicks which contain the same chemical compound (3-methyl pyrazine) that give krill its distinctive scent (additionally, they had two control conditions, consisting of slicks with other/no scents). Here, the assemblage was composed of nine species of birds and how they differed in their attraction to the slicks. After the investigators put the slicks onto a patch of ocean, birds were recorded as showing interest if they showed attention to the slick (flew near it, landed on it, etc.). The investigators found that four out of nine species were particularly attracted to the krill-scented slicks, and this appeared unrelated to how much krill is typically in the species' diet. The investigators conjectured that different bird species employed different strategies to hunt krill, relying on either olfactory, visual, or social cues (or combination of each) – and that this is linked to the typical foraging strategy of the species (e.g., whether they tend to forage in large groups or how competitive/vulnerable the species is). Another example of a study using an assemblage is from Webster and Lefebvre (2004): they investigated problem solving abilities and neophobia in five wild bird species (doves and Passeriformes) who foraged in a local neighborhood in Barbados. The investigators captured the birds in traps, habituated them, and then tested the birds. They also did

a field version of the same study (using the same general method). The neophobia test measured the birds' latency to approach food that was novel (versus familiar). The problem solving test measured the birds' ability to employ novel procedures to open a transparent box containing food. The investigators found significant differences between species both in neophobia (doves had higher neophobia) and innovative problem solving ability (Passeriformes were more successful). According to the investigators, their results supported the idea that high food neophobia in a species has some inhibitory effect on problem solving capability. In the two studies mentioned above (and many others), species assemblages are used to draw conclusions about cross-species differences based on the same test. Although the term "assemblage" is not always used, it is a central methodology in the study of animal cognition.

## Fossil Assemblages

One can look at assemblages of dead animals too. Zooarcheology is the study of dead/extinct species (Crabtree 1990). By looking at animal remains (i.e., "faunal assemblages"), it is possible to draw inferences about life in the past. For example, Crabtree (1990) showed how the study of animal remains help us to learn about the relationship between humans and animals in ancient human societies: we can learn about past human diets, meat consumption, meat trade, methods of butchery, the range of animal species used for meat and pets, age of animals at death, and even social status (e.g., wealthier people would have different consumption patterns, as reflected in their refuse collections). These types of studies are location-bound: the fossils are found at a specific field site (e.g., the remains of a human dwelling) and these form the basis of conclusions about how life had been like at that location. This is congruent with the textbook definition of "assemblage" in archaeology (Joyce and Pollard 2010): referring to objects deposited at a specific location, either intentionally or accidentally, consisting either of artifacts (such as tools) or

biological matter (such as fossil bones), which are presumed to be associated with each other due to spatial proximity within the area that they were discovered. Archeological and paleontological assemblages form a complex picture of the past (Joyce and Pollard 2010), because the natural processes of deposition rarely allow findings of whole animal fossils or perfectly intact field sites; instead, objects are typically fragmented and scattered, giving the scientist a detective's job of reconstructing the findings (e.g., piecing bones together), reconstructing the past environment (e.g., what kind of ecosystem existed at that time), and reconstructing the processes of deposition (e.g., the effects of erosion or weather on the fossils since being deposited).

Fossils can also give us insights into the behavior and cognition of extinct animals. Here, the word "assemblage" is used more loosely: less about location and more about categories. For example, Naish (2014) reviewed the fossil record of birds in order to make inferences about the evolution of bird behavior. Bird fossils excavated from many field sites can be placed into an assemblage of many bird species fitted to an evolutionary timeline (cladogram). We cannot observe the behavior of extinct birds directly: with rare exceptions, we have only their bones. One method of inference is to compare the bodies of extinct birds with living birds, using the (not always true) assumption of that birds with similar morphologies will display similar behaviors (Naish 2014). For example, if a fossil bird skeleton has the claws of a raptor and a curved beak, then the bird was probably a predator. Alternately, if a fossil bird has a smaller body and a long thin beak, then it might have been a forager who probes in mud. By combining fossil evidence with evidence on the behavior of living bird species, we can make inferences about extinct birds on their methods of foraging, their diets, methods of locomotion (e.g., whether flying or not), reproductive behavior (e.g., placement of eggshells provides clues to nesting behavior), age of sexual maturity, and sociosexual display (Naish 2014). Faunal assemblages have also been studied extensively by scientists who study the evolution of the human mind (Shultz et al. 2012; Wynn 2002). The humans who went extinct – those of the *Homo*

genus, Neanderthals, and earlier – left only sparse clues to help us understand their behavior and cognition: fossils and artifacts. Looking at hominid fossils, scientists can look at the various brain sizes calculable from the inside of fossil skulls, plotted against time and compared against likely environments, in order to draw a picture of how larger brain sizes might have evolved in conjunction with certain cognitive skills such as language (Shultz et al. 2012).

## Tool Assemblages

Finally, extinct hominids also left behind an extensive assemblage of stone tools (Wynn 2002). These have been excavated from sites going as far back 2.5 million years ago (mya), and archeologists such as Thomas Wynn (2002) have compared these artifacts against psychological theories in order to study the likely cognitive abilities of our hominid ancestors. We can compare, for example, stone tools from the Oldowan industry (roughly 2.6 to 1.7 mya) to the later Acheulean industry (roughly 1.7 to 0.1 mya) and see that the later tools had far more technical sophistication. Wynn (2002) compared these industries and made inferences about the abilities of the stone tool makers (the earlier species of humans) in their ability to understand and create symmetry (which he originally did from a Piagetian perspective). Other researchers (e.g., Haslam et al. 2009) have stressed the importance of broadening the investigation of primate cognitive evolution to many more types of primate tool assemblages, from living and extinct species (including capuchin monkeys, chimpanzees, and the various extinct *Homo* species), to develop an integrated view about how cognitive tool using abilities evolved over time.

## Associative Learning

Mauricio R. Papini and Shannon E. Conrad  
Department of Psychology, Texas Christian  
University, Fort Worth, TX, USA

## Synonyms

Classical conditioning; Conditioning; Instrumental conditioning; Operant conditioning; Pavlovian conditioning

## Introduction

Emily has been working long hours lately, so her husband Steve sends her flowers to brighten up another stressful day. Steve has made similar gestures to help Emily throughout their relationship, so she proudly displays the bouquet on her desk. Emily's coworker Erin has a different reaction. Since Erin only receives flowers when her boyfriend has something to apologize for, she immediately assumes Steve has made a mistake. The same flowers responsible for Emily's joy make Erin skeptical and worried for her friend.

Corey travels often for work and is happy to find his favorite burrito restaurant in almost every new state he visits. Today, however, he must try for a new restaurant since his favorite one is nowhere to be found. He enjoys his usual order for lunch before returning to the hotel. Later that night, Corey becomes extremely ill and wakes many times throughout the night. He struggles through work the next day and vows to never visit this new restaurant again, no matter where he might be.

Jessica wakes up late, hungover from another night of heavy drinking. She has already lost several jobs due to her tardiness, so she rushes to work thinking which excuse to use this time. Her friends can always control themselves at happy hour, but whenever she is around alcohol, it feels impossible to stop. Even seeing the empty whiskey glasses in her cabinet at home is enough to make her reach for a drink. Despite the efforts of

her family and the threat of losing yet another job, Jessica's cycle persists.

All three of these scenarios are examples of associative learning at work in which separate events become paired together. Technically the first is Pavlovian or classical conditioning. Emily's and Erin's different histories guide their reaction to flowers. The second is a powerful example of instrumental conditioning, where one evening of sickness causes Corey to stop eating in a new restaurant. Perhaps Jessica, from the third example, should have a similar avoidance response to alcohol, given that her life is falling apart before her eyes. Her behavior is still considered to be instrumental, but it has become outcome-independent or habitual.

Each of these is a familiar example for humans, but what about other animals? Do they make the same kinds of associations? This entry summarizes some of what comparative psychologists have learned about the role of associative learning in animal behavior over the last 120 years since Thorndike's (1898) PhD dissertation and Pavlov's (1927) discovery of classical conditioning. The review that follows draws from several chapters in Papini (2008).

## Basic Concepts in Associative Learning

The importance of Thorndike's PhD dissertation can hardly be overemphasized (Boakes, 1984). Thorndike is credited with bringing the study of instrumental conditioning into the laboratory. In addition, his research had a comparative emphasis. At about the same time, Pavlov (1927) was developing a training method that allowed for an objective assessment of an animal's ability to make predictions about impending events. Both Thorndike and Pavlov opened the way for a scientific study of associative learning and also established the foundation for the two forms of conditioning, instrumental and classical, respectively, that together have shaped the field. Let's start by comparing these two forms of conditioning.

The environmental conditions in which animals live vary in the extent to which they can

control them by means of their own behavior. At one extreme are situations in which the environment changes independently of the animal's actions (e.g., daily light cycles, seasonal food availability). New events may also arise as unexpected outcomes of the animal's own behavior. A foraging animal may come across a new source of food or be the target of intense aggressive behavior after stepping into the territory of a conspecific (e.g., another male of the same species). Although an animal may have no control over the situation, it can still learn to use cues and signals that predict biologically relevant events – this is called *classical* or *Pavlovian conditioning*. As a result of such learning, a signal associated to food may induce salivation and approach responses in later encounters, whereas a clue that a conspecific is present in the vicinity may elicit freezing or avoidance responses. At the other extreme are situations in which the animal's own behavior leads to resources such as food, water, and mates. This behavior is influential in the sense that it guides the animal toward or away from significant resources – this is called *instrumental* or *operant conditioning*. In this entry, associative learning and conditioning will be considered synonyms.

Three distinctions must be kept in mind when discussing associative learning: learning versus performance, procedure versus process, and phenomenon versus mechanism. We discuss each of them next.

## Learning Versus Performance

Associative learning involves the short-term acquisition, long-term storage, and retrieval of information about events that occur in close temporal or spatial *contiguity*. Although contiguity is generally necessary for associative learning to occur, some violations are known. For example, events separated by long intervals may be associated, whereas perfectly contiguous events may fail to be associated. Conditioned taste aversion after, say, pairings between the taste of saccharin and the administration of a toxin like lithium chloride (inducing gastrointestinal discomfort),

is an example of conditioning that can occur with long temporal delays between these events (Reilly and Schachtman 2009). The blocking phenomenon, that is, a stimulus reinforced in compound with a previously trained stimulus often controls little responding by itself in subsequent testing, provides an example of an apparent failure of acquisition despite temporal contiguity (Kamin 1969). *Short-term acquisition* implies an information gain through experience. *Long-term storage* refers to the consolidation of acquired information into a stable neural record. *Retrieval* refers to the reactivation of information previously consolidated into long-term storage.

A key assumption underlying this definition of learning is that learning is not the same as performance or behavioral change. Learned information can potentially change behavior, but the effect may not be immediate. A classic demonstration of this *learning-performance dichotomy* is provided by *latent learning* (Tolman and Honzik 1930). Rats preexposed to a complex maze without receiving food reinforcement explored the environment and exhibited a moderate level of behavioral change. However, when food was introduced in a goal box, preexposed animals showed faster acquisition of the correct itinerary than animals that were reinforced from the start of training. This difference suggests that preexposed animals were acquiring and storing information about the maze despite the absence of reinforcement. That information was later retrieved when food became available in the environment. Thus, although biologically salient events (e.g., food, pain) may be needed for performance, they do not appear to be required for learning to occur. The learning-performance dichotomy makes any conclusion regarding the absence of conditioning particularly problematic. Apparent failures of acquisition must be treated with caution because they may represent failures of performance. A major alternative to acquisition failure is retrieval failure, that is, the inability of the stimulus to reactivate an acquired memory, thus failing to influence behavior. Blocking is a case in point, as under some conditions, a failure of a stimulus to provoke responding when accompanied by a previously trained stimulus may reflect a

performance deficit, more than an acquisition deficit (Miller and Matzel 2006).

## Procedure Versus Process

A second distinction to be considered is that between procedure (the arrangement of events in an experiment) and process (the learning mechanism involved). Whereas classical and instrumental conditionings are easily distinguished in terms of procedures, the underlying mechanisms are more difficult to identify. Natural behavior is likely to be usually influenced by both processes simultaneously, although in the lab they can be shown to be irreducible. What are the procedural differences between these two forms of conditioning?

In a typical experiment on classical conditioning, an animal is repeatedly exposed to a sequence of two stimuli. The first is a stimulus initially neutral that has little control over the target response. This is referred to as the conditioned stimulus (CS). Using Pavlov's famous experiment, before conditioning, the metronome (the CS) elicits little or no salivation. The second stimulus is usually (but not always) a relatively intense stimulus capable of eliciting movements or autonomic responses. This is called the unconditioned stimulus (US) and the response it elicits is called the unconditioned response (UR). In Pavlov's lab, the US was usually access to food. CS→US pairings are typically presented several times within a particular session separated by an intertrial interval. Such trials endow the CS with the new ability of eliciting a conditioned response (CR). Thus, after conditioning, the metronome can elicit anticipatory salivation. The pairing of two stimuli (e.g., CS→US, CS→CS, US→US, or any similar arrangement) provides a foundation for classical conditioning.

The CS→US procedure, called *delay conditioning*, has a unique procedural property: The occurrence of the CR (e.g., salivation to the metronome) is not required for the occurrence of the US (i.e., the food). Thus, CS→US pairings are response-independent pairings, that is, they are programmed by the experimenter, irrespective of

the animal's behavior. Pavlov's dogs did not have to salivate to the metronome to receive the food; food occurred whether the dog salivated or not. This feature makes the learning-performance dichotomy especially relevant in classical conditioning. Suppose after several  $CS \rightarrow US$  pairings, the animal shows no detectable CRs, is this due to an acquisition failure or to a failure of the CS to influence behavior? Special tests may be required to detect conditioning in cases like this, such as recording physiological responses (e.g., heart rate) that may provide a more sensitive dependent measure.

In instrumental conditioning, however, reinforcement (e.g., food presentation, shock omission) depends upon the occurrence of a response. The instrumental conditioning procedure involves, therefore, response-dependent training. The terminology used in conditioning experiments depends on whether the procedure is classical or instrumental. CS, US, CR, and UR are used in reference to Pavlovian procedures, whereas discriminative stimulus ( $S^D$ ), reinforcer ( $S^R$ ), and instrumental response ( $R_i$ ) are typically used to describe instrumental procedures. The term "reinforcer" refers to the external event (e.g., food, water, electric shock), whereas the term "reinforcement" denotes the organism's reception of a reinforcer.

Miller and Konorski (1928) first noticed these procedural distinctions between classical and instrumental conditioning experiments and also suggested that the underlying processes were different. However, this hypothesis turned out to be more difficult to demonstrate. Every time an animal responds in an instrumental situation,  $S^R$  is delivered in the presence of  $S^D$ . Therefore, there is a parallel between this  $S^D \rightarrow S^R$  pairing and the  $CS \rightarrow US$  pairing of a Pavlovian situation. Classical conditioning is always embedded in instrumental conditioning, so that disentangling the two and identifying which one is the source of behavioral change can be difficult. Consider another example. Suppose you are conducting a classical conditioning experiment in which a rat receives pairings between a light (the CS) and food (the US). Every time the light is turned on, the rat orients

toward it, approaches it, and sniffs it. As the rat is sniffing the light, food is delivered according to a response-independent procedure. Does the rat sniff at the light because the light has become a Pavlovian signal for food or because sniffing is being reinforced by food? Although from your perspective this experiment involves response-independent Light  $\rightarrow$  Food pairings, from the rat's perspective it may seem as if sniffing were required for food presentations (i.e., "accidental" Sniff  $\rightarrow$  Food pairings).

A key question is whether sniffing is sensitive to the Light  $\rightarrow$  Food Pavlovian pairing or to the Sniff  $\rightarrow$  Food instrumental pairing. One way to decide between these alternatives is to introduce *omission training* on sniffing (Sheffield 1965). If a response is instrumental, then it should be sensitive to both the presentation and the omission of the reinforcer. If the rat sniffs because of Sniff  $\rightarrow$  Food instrumental pairings, then it should stop sniffing when sniffing eliminates food. Because the rat may sniff in some trials, but not in others, omission training leads to a mixture of Light  $\rightarrow$  Food trials (no sniffing) and Light-only trials (sniffing). Therefore, the omission condition must be compared with a control condition in which the rat receives exactly the same frequency and distribution of Light  $\rightarrow$  Food and Light-only trials, but independently of sniffing. This is achieved by the *master-yoked procedure* in which the behavior of one animal (the master) determines the presentation and omission of the reinforcer in its own situation and also in the situation of the other animal (the yoked). The master-yoked procedure matches the environments, but allows for variation in  $R \rightarrow S^R$  pairings, which occur only in the master's situation.

There are two possible outcomes in an omission experiment. If the behavior of master and yoked animals does not differ, then sniffing is under the control of Pavlovian Light  $\rightarrow$  Food pairings ( $CS \rightarrow US$ ) because such pairings are equated across groups. Pavlovian responses are impervious to their outcome, but sensitive to Stimulus  $\rightarrow$  Reinforcer pairings. If, however, the behavior of master animals is lower than that of yoked animals, then sniffing is under the control of instrumental contingencies ( $R \rightarrow S^R$ ).

Instrumental responses are sensitive to their outcomes (but see below).

Omission experiments show that some responses are controlled by their outcome, but others are controlled by the strength of the preceding stimulus. For example, rats exposed to pairings between a burst of White Noise (the CS) and Food (the US) exhibit an increase in the frequency of three responses during the CS: *Startle*: a sudden body movement; *Head-jerk*: head movements oriented to the food magazine; and *Magazine*: standing motionless in front of the food magazine (Holland 1979). Omission training had no effect on the startle response, an intermediate effect on head jerk responses, and a suppressive effect on magazine behavior. Therefore, some responses within the same training situation are instrumental (magazine, head-jerks) while others are Pavlovian (startle).

Whereas omission experiments demonstrate that the distinction between classical and instrumental conditioning is more than procedural, one can still ask about the reasons for these differences. Harris et al. (2013) noted that although masters exhibit less magazine than yokes, magazine behavior still increases during training. They asked whether the omission contingency reduced magazine in master animals by increasing the frequency of incompatible responses, or whether it increased magazine in yokes because of accidental pairings with food (such pairings are eliminated in masters). They tested these hypotheses by training animals in a discrimination in which one of the stimuli was master and the other yoked, but with a twist: these stimuli had a common element. If we call the stimuli A and B, then one group received  $AB \rightarrow \text{yoked}$  and  $A \rightarrow \text{master}$ , whereas the other group received  $AB \rightarrow \text{master}$  and  $A \rightarrow \text{yoked}$ . If omission (master) increases incompatible responses, then the second discrimination would be easy because such responses are associated to the unique element, B. However, if omission elevates responding in yokes because of accidental magazine  $\rightarrow$  food pairings, then the first discrimination would be easy because the unique element, B, would receive the benefit of such pairings, which could not occur in A trials because of omission. The results indicated that the first

discrimination was unsolvable, whereas the second was easy to master. Thus, there is evidence that magazine responses in master-yoked situations are reduced in masters relative to yokes not because it is an instrumental response, but because omission contingencies increase the frequency of incompatible responses.

These results have two major implications. First, even when masters perform below yokes, the response can still be Pavlovian, the difference being related to the reinforcement of incompatible responses in master animals. Second, in relatively simple situations, most behavior, even seemingly instrumental responses such as approaching a location where food delivery is impending, are controlled by preceding stimuli, rather than by ensuing outcomes. This makes behavior impulsive. As shown below, however, some behaviors are actually under the control of their outcomes, thus showing their instrumental nature (see section on “Goal-Directed and Habitual Behavior” below).

## Phenomena Versus Mechanisms

Psychologists tend to use the term “mechanism” liberally, so it makes sense to clarify it here (Bitterman 1975; Papini 2002). *Learning phenomena* are typically induced under laboratory conditions and involve a specific difference between groups or conditions in an experiment. For example, in the omission experiments described above, a distinction between master and yoked groups. The phenomenon, in this case the “omission effect” is defined by the comparison between conditions. But learning phenomena must be the result of *learning mechanisms*, that is, a set of processes intervening between environmental conditions of training and behavior. For example, the omission effect in magazine behavior was attributed to the accidental reinforcement of incompatible responses in master animals – a psychological mechanism.

The distinction between phenomena and mechanisms is relevant to comparative research on learning and cognition. Because learning phenomena are induced under laboratory conditions

and are usually defined in terms of a comparison, they are not comparable to typical biological traits such as body size. They are not even similar to behavioral traits defined in terms of their plain presence in a given species. For example, in the statement “gorillas are a polygynous species,” polygyny (i.e., a mating system in which a male defends two or more females from other males) refers to a trait present in gorillas under natural conditions. But to say that “gorillas exhibit the omission effect” would require the experimental induction of this phenomenon in a comparison between experimental and control groups. Natural observation of gorilla behavior could suggest that some aspects of their feeding behavior are controlled by current outcome value, but these observations would not demonstrate the omission effect. Therefore, because learning phenomena are not directly observable in the natural behavior of individual animals, any reference to the evolution of learning needs to center on learning mechanisms. Learning phenomena are the arena allowing comparative psychologists to understand how brain processes produce behavioral outcomes involving learning. Learning mechanisms are those processes that intervene between the external conditions (inputs) and the behavioral responses (outputs).

A clear understanding of the concept of mechanism has far-reaching implications, from an understanding of comparative research on learning and cognition to the development of animal models of human psychological disorders. Species similarities in learning phenomena of interest to both comparative and animal-model research hinge upon the evolutionary concepts of homology (similarity due to inheritance from a common ancestor) and homoplasy (similarity due to common selective pressures, but evolving independently). Although traditionally comparative psychologists have relied heavily on behavioral similarities across species, a growing understanding of the neural processes underlying learned behavior together with advances in neuroscience methods is opening the door to a more complex view of the concept of mechanism. Species similarities in learning phenomena need to be assessed in at least four mechanistic levels before the issue

of homology vs. homoplasy of learning mechanisms can be resolved (Papini 2002): psychological, neurobiological, neurochemical, and cell-molecular levels of analysis. The next paragraphs describe these levels.

The *psychological level* is the traditional level of analysis developed by comparative psychologists and involves such concepts as  $S \rightarrow S$  associations, attentional decrement, and stimulus generalization, among others. The methodology involves the dissection of effects through experimental designs involving different conditions of training. These concepts apply specifically to an understanding of learning and provide a guide to interpret the effects of behavioral manipulations at lower levels of analysis (Bitterman and Woodard 1976). Without a psychological theory, any description of the effects of brain manipulations on learning would be restricted to presence-absence statements (e.g., “this drug affects learning”). With the guidance of a psychological theory, these descriptions can be more specific (e.g., this drug interferes with memory retrieval, but not memory consolidation).

The *neurobiological level* is the level of brain circuits. An explanation of conditioning at this level requires specifying the architecture necessary for a circuit to detect  $CS \rightarrow US$  contiguity. The methodology involves lesions and stimulation of various brain regions to determine those that are involved in a given learning phenomenon. Coincidence detectors in the amygdala, hypothesized to underlie fear conditioning, are an example of a neurobiological mechanism of learning. These are brain sites in which pathways carrying information from the CS and US converge into individual neurons. Such convergence seems to be necessary for establishing  $CS \rightarrow US$  associations.

The *neurochemical level* refers to synaptic processes. Convergent pathways involved in conditioning contain many synapses that show plasticity. Synaptic plasticity is necessary for detecting coincidences such as those involving  $CS \rightarrow US$  pairings. The main methodology for studying the neurochemical basis of learning involves the administration of drugs that affect synaptic transmission, whether systemically or in

specific brain locations. Synaptic properties can also be altered by genetic manipulations. For example, gene knock-out and transgenic manipulations are used to eliminate a specific synaptic receptor.

The *cell-molecular level* includes processes occurring inside neurons that are responsible for short- and long-term cellular changes involved in learning. A major example of such processes is a second-messenger cyclic adenosine monophosphate, or cAMP (neurotransmitters are known as the first-messenger system). Second messengers are part of a cascade of cytoplasmatic changes induced by neural activation that have the property of opening some ion channels, thus modifying synaptic conductivity. Second messengers can also influence gene transcription in the cell nucleus, initiating or terminating protein production. Because gene transcription and protein synthesis are implicated in long-term memory processes, second-messenger systems play an important role as a cellular substrate of learning.

These mechanistic levels provide a criterion for assessing the homology vs. homoplasy question. If, for example, two species exhibit a similar learning phenomenon and its analysis were to demonstrate the same underlying mechanisms at all four levels, then the hypothesis of homology would be considerably strengthened. If, by contrast, different underlying mechanisms were found in at least one level of analysis, then the hypothesis of homoplasy would gain support. Although a priori this criterion seems straightforward, in reality, this would require quite an extensive line of work. As a result, the paucity of data is no surprising. However, there are some promising examples that carry the analysis into at least one level. For example, avoidance learning seems to depend on the amygdala (or its homologous structure) in rodents (Choi et al. 2010), toads (Puddington et al. 2016), and goldfish (Portavella et al. 2004). However, because these experiments were not done within the framework discussed above, their procedures are not sufficiently analogous to be on safe ground. Still, the results are consistent with homology at the neurobiological level in avoidance learning among species from three different vertebrate classes. This problem is

further treated below, but first we acknowledge some complexities of the conditioning process.

## Complex Conditioning Phenomena

Conditioning phenomena display an impressive range of complexity. From the relatively simple delay conditioning procedure developed by Pavlov (1927), some amazing capacities have been uncovered. Three such capacities will be highlighted here. First, there is extensive evidence showing that animals respond to a CS because it activates a representation of the US and its current value. These demonstrations have been based on several procedures for the post-conditioning devaluation of the US. The rationale of this *US-devaluation effect* goes like this. During conditioning, CS→US pairings endow the CS with the ability to activate a representation of the US, which then triggers the CR. Thus, devaluation of the US representation after conditioning can change the CR. In one experiment (Holland and Rescorla 1975), rats were exposed to Tone→Food pairings, and when they were responding to the Tone, they received separate Food→Rotation pairings. Rotation activated vestibular receptors in the inner ear and produced an aversive effect. Such pairings were designed to modify the incentive value of the Food from an appetitive into a less appetitive or even aversive stimulus. Finally, rats were exposed again to the Tone, and they showed reduced responding compared to groups that had received unpaired presentations of Food and Rotation. This US-devaluation effect, which has been generalized to a variety of situations, shows that activation of the US representation when it has become less appetitive now fails to control similar levels of performance to those of control groups.

Animals apparently can also associate actual events with the reactivated representation of an absent event (Holland 1981). Rats exposed to Tone→Food pairings were later given pairings between the same Tone and a toxin that produces gastrointestinal discomfort (lithium chloride, LiCl). Thus, if the Tone reactivated a representation of the Food when the animal was made sick

by LiCl, that Food representation would be paired with sickness and, as a result, the animal should develop an aversion to the Food. Subsequent tests showed that rats consumed significantly less food than in a variety of control conditions. This phenomenon, known as *representation-mediated learning*, suggests that the representation of a stimulus has similar properties as its presentation.

Finally, a phenomenon known as *occasion setting* suggests that a stimulus (called an occasion setter, OS) may be associated not just with another stimulus (as shown by the US-devaluation effect), but with a [CS→US] association as a whole (Schmajuk and Holland 1998). The idea is that the OS bears a hierarchical relationship to a [CS→US] unit, rather than linking directly to just the CS or the US. OSs are typically diffuse stimuli lasting longer than CSs that do not acquire the capacity of eliciting responses by themselves; however, the animal responds to the CS only when this is presented in the context of the OS, so they can instigate responding. Furthermore, the simple presentation of the OS by itself, an operation analogous to extinction, does not affect its ability to influence the CS.

These complex effects highlight a major point about conditioning: with a seemingly simple mechanism (associative links), the brain can produce relatively complex outputs. Associative learning is sometimes dismissed on the assumption that it cannot possibly provide a workable explanation for complex behavior – an assumption that needs to be considered carefully in specific cases.

## Goal-Directed and Habitual Behavior

Behavioral change occurs when signals and responses are paired with outcomes. For example, Jessica (from one scenario presented in the introduction) learned to seek out for alcohol because of its taste, the social context accompanying alcohol drinking, and alcohol's ability to reduce negative emotions. These kinds of acquired behaviors, that is, those that occur as a result of seeking a favorable outcome, are referred to as *actions*. The main property of actions is that they are outcome-

dependent behaviors – behaviors controlled by current outcome value. However, Jessica's relationship with alcohol changed in time. Instead of alcohol intake always producing favorable consequences like it did in the beginning, Jessica's life is being taken over by the drug. Even in the face of losing jobs and friendships, she is unable to control her alcohol intake. Acquired behaviors that persist despite being followed by negative consequences are called *habits*. An important property of habits is that, at least in the short term, they are outcome-independent behaviors – behaviors controlled by preceding stimuli, rather than by outcomes. Under some conditions, extensively practiced actions tend to become habits, with the outcome guiding behavior early on and habitual patterns becoming “automatic” responses to stimuli or situations later on.

Understanding the transition from action to habit is relevant to the treatment of several psychological disorders. For example, substance use disorders, obesity, and compulsive behavior each have a learning component and are difficult to treat even in clinical settings. After extensive practice, typical actions such as magazine approach in rats or sharing an after-work drink in people can become automatic habits. In extreme cases, strongly ingrained habits may prevent a person to live a normal life. Once these addictive behaviors are habitual, they are insensitive to even the most aversive consequences, even when repercussions include a person's health and social life, job security, and legal status (Hogarth and Chase 2011).

In the laboratory, testing to determine whether a behavior is an action or a habit can be done using a number of reward devaluation procedures. An outcome-dependent behavior should be influenced, for example, by the organism's motivational level or by knowledge of the current value of the outcome. One way to modulate motivational levels in the laboratory is by using a satiation manipulation. If rats are instrumentally trained to work for food, food-deprived animals would show faster changes in behavior than free-fed animals. Organisms that are not hungry will not be as motivated to respond as hungry animals when working to obtain food.

Another procedure used to differentiate between actions and habits in the laboratory is to alter the value of the reinforcer by associating sickness with the outcome of a behavioral response either early or late in training. Adams (1982) used sickness to devalue the food outcome at different points in training to better understand habit formation. When food was paired with the toxin lithium chloride to make rats sick after eating, early in training they were less likely to press a lever previously associated with food. This result suggests that lever pressing during early training was dependent on their memory of the current value of the food. However, when the same toxin was administered after extensive training, animals responded to the lever as much as controls. The persistent behavioral response to work for food that had made the rats sick implies that, late in training, lever pressing was less dependent upon current reward value or, in other words, that this behavior had become habitual. It is likely that this shift from action to habit also involves a change in the underlying circuitry controlling behavior (Balleine and O'Doherty 2010; Gasbarri et al. 2014). For example, in rats, lesions of the dorsomedial striatum leave the animal less sensitive to outcome devaluation (suggesting this area is important for actions), whereas lesions of the dorsolateral striatum make behavior more vulnerable to outcome devaluation even after extended training (suggesting this area is important for habits).

Habitual behavior that seems to be independent from current outcome value is typically observed in nonmammalian vertebrates in situations involving reward devaluations. For example, toads trained to traverse the length of a runway to access a large amount of water typically acquire this behavior faster than toads reinforced with a small amount of water. This demonstrates that different reward magnitudes can affect their instrumental behavior. However, after a devaluation from a large to a small reward, toads simply adjust their instrumental behavior, instead of rejecting the smaller reward (Muzio et al. 2011). Placed under similar conditions, mammals tend to reject the devalued reward (Papini 2014). One possible interpretation of these results is that the

behavioral flexibility shown by toads in learning situations is based on habit formation, whereas that exhibited by mammals can be action or habit learning depending on the conditions of training.

## Species Similarities and Differences in Learning Phenomena

The emphasis on mechanistic levels suggested above leads to a rule that can be applied to postulate homologies and homoplasies in learning mechanisms across species (Papini 2002). Homology requires that learning phenomena observed in two different species are dependent on the same mechanisms at all levels of analysis (i.e., manipulations of training parameters, neurobiological structures, neurochemical systems, and cell-molecular processes). One would expect that homologous learning phenotypes would be more likely in closely related species. By contrast, homoplasies should be more common among distantly related species. Advances in molecular genetics since the 1980s have uncovered an unexpected degree of homology even among distantly related species (see Papini 2008). Phenotypic change is often achieved by the recruitment of old genes and molecules in the organization of new structures and functions. What are the implications of these discoveries for an understanding of learning?

Notice that mechanistic levels are hierarchically nested. Thus, a specific cell-molecular module may be activated by the operation of different neurotransmitters, in different neurobiological sites. If molecular mechanisms are generally conservative, as suggested by genetics, then one would expect a relatively stable set of cell-molecular processes involved in learning even among distantly related species. One implication is that parallel evolution of learning mechanisms should be relatively common among animal species. Constraints on the ability of molecular pathways to induce synaptic plasticity at lower mechanistic levels may result in the parallel evolution of similar learning capacities at the behavioral level. Similar learning phenomena in

different species (or in the same species, but across different conditions) may be based on different neurotransmitter systems and yet share the same cell-molecular processes for synaptic plasticity. The task for comparative psychologists is to determine whether species similarities in learning phenomena are superficial (homoplasy), based on common cell-molecular processes even if involving different processes at the neurobiological or neurochemical levels (parallel evolution), or indeed based on the same mechanisms at all four levels of analysis (homology).

When different learning phenomena are found in different species, the key question is whether the underlying mechanisms (as defined above) have diverged and the main alternative hypothesis maintains that the behavioral differences are caused by differences in contextual mechanisms. Contextual mechanisms are processes other than learning that can also affect behavior, including sensory-perceptual processes, motivation, and motor control (Bitterman 1975). Going back to our earlier scenarios, Corey may stop eating burritos in that particular restaurant because he acquired an aversion or because he is not hungry or does not know how to get to that restaurant. Such *contextual variables* can influence behavior independently of learning. Therefore, species differences in learned performance must discard alternative accounts based on the action of contextual variables before a hypothesis of a divergence in learning mechanisms can be accepted. This is the learning-performance dichotomy applied to species comparisons.

A major obstacle for comparative research on learning originates in the impossibility of equating contextual factors across species. For example, if rats and turtles are reinforced with three food pellets for traversing a runway and rats show better performance, is it because the rat's learning mechanisms are more efficient or because three pellets have a greater motivational impact for the rats than for the turtles? Perhaps turtles reinforced with six pellets would perform at the same level as rats. It is virtually meaningless to compare different species in absolute terms. The approach favored by comparative psychologists consists of comparing species in terms of how their behavior

in analogous situations responds similarly to similar manipulations of training variables. Thus, instead of asking whether the rat learns the runway task faster than the turtle, one would ask whether runway learning depends on the same set of variables in rats and turtles. For example, although rats and turtles may perform at different speeds, acquisition may improve in both species as reinforcer magnitude increases. This direct relationship between acquisition rate and reinforcer magnitude implies that depending on the training parameters, acquisition may be faster in rats or in turtles. This method is called *control by systematic variation*. Variables suggested by empirical or theoretical considerations to be important determinants of learned behavior, such as reinforcer magnitude, can be systematically manipulated across species to determine whether the behavioral adjustments are similar or dissimilar.

Discovering homologies/homoplasies in learning mechanisms requires extensive analysis of similar learning phenomena across species, at all levels of analysis. However, discovering divergence in learning mechanisms across species requires extensive analysis of the potential role of contextual factors in the target learning phenomena, in each species. It is no surprise that the comparative analysis of learning, from an evolutionary perspective, is at the beginning of the twenty-first century still in its infancy.

## Problem Solving

As shown above, associative learning involves a wide range of phenomena, from simple to complex, and it is also dependent on a diversity of mechanisms. But is conditioning, with all its complexity, sufficient to account for complex cases of behavior? This question has been pursued in the context of problem-solving behavior – the ability displayed by animals when placed in situations requiring novel and even creative behavioral strategies.

The work of Thorndike (1911) and Köhler (1925) gave rise to an influential controversy about the nature of learning. Thorndike's (1898)

experiments on the acquisition of new skills by a variety of species led him to suggest that learning progressed gradually as a result of a trial-and-error process – instrumental conditioning. For example, cats exposed to a puzzle box, in which the operation of a latching device allowed them to open the door and have access to food, showed a gradual decline across trials in the time taken to open the door. This view was contradicted by experiments that showed that animals can acquire a new skill suddenly and abruptly by *insight learning*. Köhler (1925) reported experiments with chimpanzees in which, as in Thorndike's puzzle box situation, access to a piece of food required a relatively complex sequence of responses. In a famous experiment, a male chimpanzee named Koko was shown an unreachable piece of fruit hanging from the ceiling of his cage, together with a familiar small box. Initially, Koko displayed attempts at reaching the fruit, but paid no attention to the box. After a few trials, Koko exhibited a variety of behaviors toward the box: he threw it, sat on it, and directed violent attacks to it. In a subsequent session and after a few unsuccessful attempts at reaching the fruit, Koko turned toward the box, seized it, dragged it beneath the fruit, stepped on it, and took the fruit. Koko and other chimpanzees used by Köhler exhibited insightful behavior only after extensive practice with all the elements involved in the problem-solving situation.

Consider again the insight situation, only this time with a pigeon as the subject. Epstein (1987) separately trained four different responses by reinforcing each with food according to regular procedures of instrumental shaping. The pigeon was trained to push a small cardboard box toward a green spot on the floor, to open the door of an enclosure, to step on a cardboard box fixed in a particular location, and to peck at a plastic banana. Only the object appropriate to the performance of the response being shaped was present during a given session (e.g., the cardboard box when reinforcing pushing). In a test session, the movable box was placed inside the enclosure and the banana suspended out of the animal's reach and over the test apparatus. The pigeon started by stretching toward the plastic banana, then it approached and pecked the door until it opened,

and about a hundred seconds into the session, the pigeon started to push the cardboard box that had been placed inside the enclosure in the direction of the plastic banana. When the box was about midway between its original position and the plastic banana, the pigeon stepped on it and stretched toward the plastic banana, but it could not reach it. Finally, the pigeon pushed the box a bit further, climbed on it, and pecked at the plastic banana. The entire sequence took 237 s. Although the individual components of this response sequence were trained in isolation, the test situation induced their spontaneous interconnection.

The outcome of this experiment with a pigeon is reminiscent of Koko's insightful problem-solving behavior and suggests that such a capacity is not restricted to primates. But do these animals understand that moving the box will allow them to stand on it right underneath the fruit and thus obtain a reward? If they understand the nature of the problem, then a pigeon trained as described and given a choice between two similar boxes would push the one on which it can stand (the other, nonfunctional box lacked the top surface). Cook and Fowler (2014) replicated Epstein's results, but also showed that pigeons would push either box underneath the unreachable target, thus suggesting they did not understand that stepping on the box was a means to reach the target.

A number of training paradigms have been developed that exploit the ability of animals to transfer previously acquired information into new situations. These paradigms illustrate the effects of extensive problem-solving training on the adjustment to new situations in a more systematic fashion than that characterizing the experiments reviewed above. In the *learning set* paradigm, animals are trained in a sequence of simple discriminations, each one involving a pair of stimuli. In each case, choice of one of the two stimuli is reinforced with food, whereas choice of the other is not reinforced. While the resolution of the initial discriminations is achieved gradually by a process of trial-and-error, eventually the animal's behavior can become insightful. A sophisticated animal facing a new two-choice discrimination after having successfully solved many similar problems may behave as if it were

following a *win-stay, lose-shift rule* (Harlow 1949). A reinforced choice implies that the other option is not reinforced and therefore it should keep choosing the same stimulus in future trials (i.e., win-stay). By contrast, a nonreinforced choice implies that choosing the other option will be rewarded (i.e., lose-shift).

Learning-set studies confirmed the importance of contextual variables. Rats trained to discriminate between two-dimensional visual stimuli perform poorly, even after hundreds of problems, but with tridimensional visual stimuli, spatial locations, or olfactory stimuli their performance is comparable to that of primates. Therefore, the performance of any given species in the learning set paradigm reflects not only learning skills, but also the animal's efficiency at representing the stimuli involved in the task. Such sensory-perceptual contextual factors may be responsible for the correlation between learning set performance and neocortical size reported in a large study involving primates (Rumbaugh and Pate 1984).

These experiments on discrimination learning illustrate a major point in learning theory, namely, that the development of complex problem-solving skills, including rule learning, is the ending point of a long history that starts with conditioning. Animals that have been exposed to a wide variety of situations and problems become capable of achieving new levels of processing that appear to be beyond associative learning, such as making inferences and developing rules. Rules are efficient ways of short-cutting what would otherwise be a lengthy accumulation of experience through trial-and-error. From the perspective of such cognitive processes, associative learning becomes a contextual factor. Attempts at showing such capacities must demonstrate that the behavior under study cannot be accounted for in terms of associative learning.

## Conclusions

Three scenarios were suggested at the outset to illustrate instances of associative learning. For Emily and Erin, the same object (flowers as a

present for Emily) was positive or negative depending on their prior experience. Signals for positive or negative events (e.g., food and pain) can become themselves positive and negative, and, in such capacity, they can operate as conditioned reinforcers. Corey had a negative experience in a restaurant and that shifted him to an avoidance mode for that location. Negative events can lead to escape and avoidance conditioning, a type of learning that has obvious protective effects, but can also lead to maladaptive behavior, as when a person suffers from a phobia – an extreme fear response to an object (e.g., spiders) or situation (e.g., outdoors). Jessica represents the opposite extreme. She has negative experiences related to an alcohol addiction, but the pulling from signals of alcohol is so powerful that her behavior has become automatic. In a sense, Jessica suffers from impaired avoidance learning.

These examples illustrate the widespread reach of associative learning processes that affect the behavior of organisms. Although they are represented here in terms of human behavior, many of these effects have been demonstrated in experiments with other species, including what might be considered relatively simple species based on behavior and neural organization. It is impossible to cover all relevant topics on associative learning in one encyclopedia entry, so readers are encouraged to search for other entries and additional related readings for a deeper understanding of learning phenomena and mechanisms.

## Synonyms

[Associative learning](#)

## Definition

An association refers to a connection between concepts, ideas, events, and mental states. Associations usually develop through specific experiences or observations. Associations first became a philosophical topic with Plato and Aristotle in 350 BCE. Later, the English empiricists revived the idea and applied it to their explanations of behavior, thought, and memory. In modern psychology, associations play a role in Pavlovian and operant conditioning (aka instrumental learning). The ability to form associations between neutral stimuli and biologically relevant stimuli or events was likely a key behavioral influence in early

evolution. Associative learning has been established across a wide range of vertebrates and invertebrates. More recently, the study of associative mechanisms has been extended to include connectionist neural networks and modern cognitive and behavioral neuroscience.

## Aristotelian Associations

The idea that specific laws govern the formation of association in the mind began with Aristotle in 350 BCE. They included the laws of contiguity, similarity, and contrast. Aristotle posited that memory (and, by extension, thought) depends on the ability to form such associations. He also argued that any animal that can perceive time is capable of memory and, therefore, of forming associations.

**The law of contiguity** states that two events or thoughts that regularly occur close together in time or space will become associated, making it easier to recall one in the presence of the other. A common example is the tendency to think of thunder whenever there is lightning because both tend to occur close together in time.

**The law of similarity** states that when two events or thoughts are similar to each other, the presence of one will tend to lead us to recall the other. For example, when we are offered a cup of coffee, we may also think of tea because they are similar.

**The law of contrast** states that the presence of one event or thought may bring up the memory of its direct opposite. When we hear the word “dog,” we also think of “cat.”

Aristotle’s laws of association would become the basis of modern learning theories for over 2000 years (Henley 2019). They provided a foundation for the British empiricists of the seventeenth and eighteenth century. Later, they would become the root of early twentieth-century psychological philosophies of associationism, behaviorism, psychoanalysis, and structuralism (e.g., Pavlovian associative learning, Watson’s stimulus-responses psychology, Skinner’s instrumental conditioning, Freud’s word association exercise, and Titchener’s interaction of mental elements). Today,

these same basic laws can be found in the modern study of memory, learning, and modern behavioral neuroscience.

## Associationism and the British Empiricism Movement

Associationism is a theory that defines the association as the fundamental construct of higher mental experience. Although its bottom-up approach emphasizes associative learning, it extends beyond the simple association to place associations at the core of mental reasoning. It attempts to explain complex ideas from smaller experiential units through mental association. Throughout the Age of Enlightenment, accepting simple associative learning as a core feature of thought did not necessarily preclude acceptance of the entire theory of associationism.

British empiricism was a major philosophical movement during the seventeenth and eighteenth centuries that began with Sir Francis Bacon (b.1561–d.1626). Bacon argued that only through direct observation could the truth (aka facts) be discovered. Bacon's (1620/1902) empiricism meant that only inductive reasoning could produce overarching knowledge and that only through rigorous scientific practice would the acquired knowledge lead to a better society. His emphasis on observation and empirical evidence laid the foundation for a more inductive approach to knowledge upon which the empiricists would develop their own views on associations.

**Thomas Hobbes** (b.1588–d.1679). Following in Bacon's footsteps, Hobbes, a contemporary of Galileo and Descartes, became known as the founder of the British empiricism movement (Henley 2019). Although he favored deduction over Bacon's induction, he too emphasized experience. It was Hobbes who brought back Aristotle's laws of association, even adding several of his own, including the laws of cause and effect, and resemblance. Many subsequent empiricists accepted the notion of the association as the basis of complex thought.

**John Locke** (b. 1632–d.1704) would have the greatest influence on the empiricism movement

and on his contemporaries. In his treatise, *An Essay concerning Human Understanding* (1689/1824), he too rejected nativism, and described the mind as a blank slate, or *tabula rasa*, upon which experience and observation established the ideas and concepts of human knowledge. Although he rejected formal associationism, he later argued that simple ideas could be associated in the mind and formed into more complex ideas.

Simple ideas, the materials of all our knowledge are suggested and furnished to the mind. . .by sensation and reflection. When the understanding is once stored with these simple ideas, it has the power to repeat, compare, and unite them, even to an almost infinite variety, and so can make. . .new complex ideas. (Locke 1689/1824)

However, Locke distinguished between natural associations and accidental associations that he said explained faulty logic that opposed reason. He suggested spurious associations, formed only as a result of contiguity, produced superstitious beliefs, such as aversions to foods, activities, or even a fear of the dark.

The ideas of goblins and sprites have really no more to do with darkness than light: yet let but a foolish maid inculcate these often on the mind of a child, and [...] he shall never be able to separate them again so long as he lives, but darkness shall ever afterwards bring with it those frightful ideas [...]. (Locke 1689/1824)

These same "spurious" associations would later be recalled to form the basis of Pavlov's associative learning over a century later.

**George Berkeley** (1685–1753) was an ordained Irish deacon of the Anglican Church who opposed materialism altogether. For Berkeley, the increasing reliance on materialism threatened the position of God in the understanding of the human mind. He challenged Locke's view by arguing that experience was nothing more than a collection of perceptions. Still an empiricist, who agreed that knowledge is constructed from ideas, Berkeley used associations to explain the reconstruction of objects in the mind. He proposed that each sensory system provided distinct, perceptual information about an object. Vision, smell, touch, hearing, and taste provide only pieces of information connected to an object. Repeated experiences

provided the opportunity to associate these distinct parts into a meaningful whole in the mind. For Berkeley, the objects that we perceive are simply associated aggregates of individual perceptions.

**David Hume** (1711–1776) was a Scottish philosopher who followed in the empirical traditions of Bacon, Hobbes, and Locke. He too believed that the content of the mind derived from experiences. Like George Berkeley, he believed that experiences were nothing more than perceptions—that we have no direct physical contact with the world. Nevertheless, these perceptual experiences provide the basic building blocks of complex ideas.

Hume was a true proponent of associationism; he viewed associations as the force behind the development of highly flexible ideas. Hume emphasized three laws of association: (a) the law of resemblance, defined as the tendency to associate events or thoughts that are similar to each other; (b) the law of contiguity, defined as the tendency to associate event or ideas that occur together in space or time; and (c) the law of cause and effect, defined as associations between an outcome and the events that precede it.

Other empiricists added to the debate on the role of associations in human knowledge, thinking, and behavior. **David Hartley** (1705–1757) proposed that all behavior begins as a reflex. Involuntary behaviors gradually become associated with specific ideas or stimuli that acquire the ability to elicit the behavior in a manner that again foreshadowed the work of Ivan Pavlov a century later. **James Mill** (1773–1836) introduced the idea of the strength of an association. He argued that frequency and vividness played a role in determining the strength of an association. For **Alexander Bain** (1818–1903), the mind consisted of feelings, volition, and intellect. He suggested that the law of contiguity governed the associations that linked these three mental aspects with behavior. “Actions, sensations and states of feeling, occurring together, or in close succession, tend to grow together, or cohere, in such a way that, when any one of them is afterwards presented to the mind, the others are apt to be brought up in idea” (Bain 1855, cited in Harned 1985).

## Russian Medicine, Physiology, and Associations

By the middle to late nineteenth century, philosophical support for “association formation by means of contiguity” had spread throughout Western Europe. But in Russia, a brewing discontent with philosophy led to its prohibition in institutions of higher learning. According to Nemeth (2001), the ideas of social reform associated with the European Age of Enlightenment led to revolts that threatened the Russian autocracy. In 1848, Czar Nicholas I censored the teaching of philosophy in all institutions of higher education in an attempt to protect Russia from “intellectual infection.” Although psychology was still allowed, the moratorium on philosophy remained intact until 1863, and did not begin to recover until 1889 (Koretzky 2013; Nemeth 2001).

**Ivan M. Sechenov** (1829–1905). Despite the censorship on the teaching of Western philosophies, progress in medicine and physiology prevailed in Russia. Sechenov (1863), promoted a purely mechanistic version of overt and mental behavior. In his account of mental life, he argued that all behavior was reflexive. The difference between humans and animals was that human reflexes could be elicited by thoughts. Initially perceived as a serious potential threat to the censorship on philosophy, the Russian courts ultimately decided that his work was presented as pure science, and as such did not technically violate the moratorium on revolutionary philosophical ideologies because of its mechanistic approach (Koretzky 2013). This opened the door for his student Ivan Pavlov to begin his investigations into the conditional nature of reflexive salivation.

## Pavlov’s Associative Learning

**Ivan Petrovich Pavlov** (1849–1936) was a Russian physiologist and student of Sechenov. His research cemented a permanent place for the “association” in modern animal learning and prompted the rise of behaviorist learning theory in American psychology (see Fig. 1). His classical conditioning method (see Fig. 2) provided a

**Associative Mechanisms, Fig. 1** Ivan Petrovich Pavlov (Public Domain). (Photograph of Ivan Pavlov. Photographer unknown. This image is in the public domain. Retrieved from [https://en.wikipedia.org/wiki/Ivan\\_Pavlov#/media/File:Ivan\\_Pavlov\\_NLM3.jpg](https://en.wikipedia.org/wiki/Ivan_Pavlov#/media/File:Ivan_Pavlov_NLM3.jpg))

paradigm for the development of concrete, measurable associations between a neutral stimulus and a biologically relevant stimulus. In his seminal work on the salivary reflex in dogs, Pavlov surgically implanted a cannula next to the oral salivary gland so he could directly observe salivation during his experiments. He noticed that the dogs would begin to salivate prior to the introduction of food into the mouth. Merely the sight of the food was sufficient to produce salivation. This observation led him to experiment with other stimuli such as a metronome and tuning forks. In each case, he reported that after repeatedly presenting an otherwise neutral stimulus prior to the introduction of food, the stimulus would gradually begin to elicit “psychic secretions” (Domjan 2015).

Pavlov called these responses *conditional reflexes* because their ability to elicit salivation was conditional on the formation of a neural connection or association between the neutral stimulus and the reflex’s biological releaser. Being a physiologist, his explanation for classical conditioning hinged on a neural process in which a neutral stimulus (NS) could become a substitute for the unconditional stimulus (US, or natural elicitor of the reflex).

According to this view (see Fig. 2), the US naturally stimulates the US brain center

**Associative Mechanisms, Fig. 2** Diagram of Pavlov’s classical conditioning method. A neutral stimulus (NS: bell) is paired with a biologically relevant, unconditioned stimulus (US: food). Food naturally elicits salivation in dogs; bells do not. However, after repeated NS/US pairings, an association between the NS and the US develops, such that the bell alone (now a conditioned stimulus or CS) will elicit salivation on its own. This

responsible for producing the unconditioned reflex (UR). The introduction of a NS simply stimulates only the brain regions that process that information. However, over many contiguous pairings of the NS and US together, a neural connection or association develops that gradually allows the previously NS to directly stimulate the US brain center. The result is that the NS is no longer neutral (with respect to the reflex). It has become a conditional stimulus that could now directly produce the reflex (now called a conditional response or CR). This explanative reasoning became known as Pavlov's stimulus substitution theory. His reasoning formalized a physiological mechanism for the formation of an association. His work legitimized the study of reflexes in Russia and initiated empirical/behavioral investigations into the associative processes responsible for simple learning.

In 1903, Pavlov presented his preliminary findings in a lecture at the 14th International Medical Congress in Madrid, Spain (Bandrés and Llavona 2003) entitled *Experimental Psychology and Psychopathology in Animals*. In 1904, Pavlov earned a Nobel Prize for his work in physiology, becoming the first Russian scientist to receive a Nobel award. In his acceptance speech, he foreshadowed John B. Watson (1913), calling for a more empirical, scientific psychology (Fig. 3).

Only by observing this condition would the results of our work be regarded as fully conclusive and as having elucidated the normal course of the phenomena. (Pavlov 1904)

After publishing his findings in English (Pavlov 1924), Pavlov's findings spread throughout the European and American psychological community. Associative learning would go on to

# Associative Mechanisms,

## Stimulus Substitution Theory

a) US activation of US brain region leads directly the UR

b) Pairing of NS and US activates both regions and allows for a neural connection to develop

c) After repeated pairings, the NS becomes a CS, capable of stimulating the US brain region and producing a CR.

spark over a century of research in the study of reflexology in Russia and, ultimately, lead to the development of a strong American tradition of classical conditioning research in psychology.

## The Association and American Behaviorism

**John Broadus Watson** (1878–1958) was an American psychologist trained at the University of Chicago where he initially studied the relationship between brain myelination and learning in rats (see Fig. 4). As part of his educational training, Watson read Pavlov's writings and found inspiration that would lead him to write his behaviorist manifesto: *Psychology as the Behaviorist Views It* (1913). As Pavlov had done before the

turn of the century in Russia, Watson (1913) posited that psychology was a purely objective science. By 1920, his stimulus-response theory of behavior, an extension of Pavlov's stimulus substitution theory, became the first real behaviorism in America. Of course, early American behaviorism was little more than a revival of the dualism of the British empiricists manifest in modern experimental methods, and again the driving force was the association.

Historically, Watson's translation of Pavlov's associationism into a broad stimulus-response behaviorism would ultimately pave the way for Skinner's operant conditioning that was less reliant on the formation of unseen associations between stimuli and reflexes (see B. F. Skinner, ▶ "Instrumental Learning").

## Comparative Classical Conditioning

The majority of research on associative learning has been conducted using mammals in the laboratory, including primarily rabbits, rats, and mice. Evidence of associative learning, using Pavlovian techniques across a wide variety of species within the kingdom Animalia (both in the laboratory and in zoos and aquaria), has secured Pavlovian mechanisms as a fundamental learning process. Table 1 presents examples of laboratory-based associative learning across a variety of taxonomic categories.

Recently, Domjan and Krause (2017) have provided a convincing, functional, and evolutionary account of classical conditioning. All behavioral mechanisms evolved as valuable mechanisms for adaptation. The breadth of interspecies ability to be classically conditioned supports the notion that forming associations is key to survival in the animal world. In short, the ability to form associations between salient CS stimuli and critically important US stimuli like food, mates, toxins, illness, rivals, etc. may confer advantages that may have historically served as a selection mechanism.

Ginsburg and Jablonka (2010) argue that conditions favoring increasingly complex nervous systems during the Cambrian era would have also favored classical conditioning as a functional

mechanism for selection. Comparative evidence is consistent with this perspective (see Table 2, derived from implications in Domjan & Krause). The extensive comparative evidence of associative learning extending widely across phyla suggests that a comparative assessment of the functional and evolutionary value of classical conditioning is a reasonable one and warrants further investigation.

## Modern Associative Learning Theory

Interest in associative mechanisms resurged in the latter third of the twentieth century with renewed enthusiasm for a quantitative analysis of classical conditioning, spearheaded by behavior analysts Rescorla and Wagner (1972). The development of associative strength in an otherwise neutral stimulus lies at the heart of associative learning.

**Associative Mechanisms, Table 2** Examples of naturalistic US/CS pairings that may have provided evolutionary value favoring associative learning as a functional behavior system.

| US stimulus                | UR response                                                | CS stimulus                                      | CR response                                         | Function                                        |
|----------------------------|------------------------------------------------------------|--------------------------------------------------|-----------------------------------------------------|-------------------------------------------------|
| Food, water                | Salivation, eating                                         | Visual contact with item or correlated cue       | Sign tracking, salivation                           | Increases digestion, improves foraging success  |
| Sickness                   | Regurgitation                                              | Flavor                                           | Item avoidance                                      | Reduced risk of toxic poisoning                 |
| Pain inflicted by predator | Species-specific response: freeze, run, hide, defend, etc. | Visual contact with predator                     | Escape, avoidance                                   | Reduced risk of predation                       |
| Pain inflicted by opponent | Species-specific response: pursue, fight                   | Visual contact with opponent                     | Visual threats, anticipatory attack                 | Increased probability of deflection of opponent |
| Sexually receptive partner | Sexual arousal, sexual behavior                            | Olfactory or auditory stimuli, context, location | Anticipatory response, sign tracking, goal tracking | Increase reproductive success                   |
| Mother-infant interactions | Grooming, milk letdown response                            | Olfactory cues, auditory cue, social cues        | Anticipatory milk letdown and release               | Increased infant survival                       |

The Rescorla-Wagner model of classical conditioning attempted to quantify how associative strength accumulates in the CS over trials. In short, as Pavlovian conditioning trials proceed, the US progressively imparts associative strength to the CS.

**The Rescorla-Wagner equation:**

$$\Delta V_n = \alpha\beta(\lambda - \Delta V_{n-1}),$$

where:

- $\Delta V_n$  is the change in associative strength imparted from the US to the CS on trial  $n$ .
- $\alpha$  is the salience of the CS stimulus.
- $\beta$  is the salience of the US stimulus.
- $\lambda$  is the maximum associative strength available for the US.
- $\Delta V_{n-1}$  is current associative strength already acquired by the CS on all previous trials.

To better understand the equation, we must first review the assumptions made by the model.

**Rescorla-Wagner Assumptions:**

1. Associative strength is acquired in a cumulative fashion. The association gets progressively stronger across conditioning trials.

2. Only a limited amount of associative strength can be imparted to the CS by the US. Called the asymptote of association ( $\lambda$ ), this upper limit is fixed and is determined by the salience of the US.
3. The saliences of the CS ( $\alpha$ ) and the US ( $\beta$ ) are constants in the equation. In any given (laboratory-based) conditioning scenario, it is assumed that the CS and the US will not change.
4. The associative strength gained by the CS on any trial is merely a percentage ( $ab$ ) of the total associative strength remaining after all previous trials.
5. Any change in the associative strength depends on how strongly the US is predicted by the CS. In simple terms, the more surprising the CS-US relation is, the greater the percentage of learning on each trial will be.

**Successful Predictions**

In addition to making accurate predictions regarding traditional Pavlovian conditioning, the Rescorla-Wagner model also predicts several

well-known phenomena found in classical conditioning. For example:

1. The model accurately predicts a negatively accelerating learning curve during standard classical conditioning.
2. The model accurately predicts a negatively decelerating learning curve during extinction.
3. The model accurately predicts certain classical conditioning phenomena including Pavlovian extinction, inhibitory conditioning, the blocking effect, and the overexpectation effect.

### Strengths and Shortcomings of the Model

*Strengths.* The Rescorla-Wagner model has enjoyed noteworthy success and respect within the scientific community due to several strengths. It uses language that is intuitive and appealing across various scientific disciplines, such as biopsychology and neuroscience. The model successfully predicts a number of well-known Pavlovian effects while requiring few independent variables, and it has few free parameters. It generates clear, testable ordinal predictions and has generated substantive research.

*Shortcomings.* The Rescorla-Wagner model remains silent (failing to make specific testable predictions) with respect to certain phenomena related to Pavlovian conditioning. Examples include (a) temporal relations between the CS and the US, (b) CS pre-exposure which typically slows learning, (c) spontaneous recovery following extinction, and (d) sensory preconditioning.

In nearly five decades, the Rescorla-Wagner model has undergone significant adjustments, but at its core, the quantitative, associative mechanism model remains a powerful, quantitative explanation of associative mechanisms. Alternative models have been proposed, including the Mackintosh (1975) model and the Pearce-Hall (Pearce and Hall 1980) model that addresses some of the issues neglected by the Rescorla-Wagner (1972) model. However, since its inception, the Rescorla-Wagner model has successfully

maintained the science of Pavlovian associations in the forefront of modern learning theory and research.

### Associations and Operant Conditioning

Operant conditioning is also considered dependent on the formation of associations, specifically between contexts, discriminative stimuli, responses, and consequences. The efficacy of operant conditioning in many nonhuman animals is directly affected by temporal contiguity in ways that suggest that the ability to form an association is sensitive to the timing of these associative elements. In fact, some researchers argue that operant stimulus control reflects both classical and operant elements (Weiss 2014). Although a comprehensive review the research related to the formation of operant associations is not possible here, Williams (1975, 1978, 1999) provides illustrative examples of the unique nature of operant associations.

Just as temporal contiguity alone does not ensure associative learning (Kamin 1969), Williams (1999) highlights the phenomenon of operant blocking as evidence that temporal contiguity alone is insufficient to establish an operant association. In classical conditioning, when a US is already fully predicted by CS1, the classical conditioning of a second stimulus (CS2) is ineffective (see Domjan 2015; Kamin 1969). This phenomenon is consistent with, and predicted by, the Rescorla-Wagner model. Williams (1999) notes that operant research has been consistent with this effect as well and argues that the ability to block response-reinforcer associations is consistent with the idea that temporal contiguity alone is not sufficient for the formation of response-reinforcer associations as well. However, operant blocking has been found to exhibit some unique qualities, independent of Pavlovian blocking.

When presented with a 5-s response-contingent keylight (SD1) followed by food after 10 s, pigeons responded reliably to the stimulus (Williams 1975) – evidence that an operant (response-reinforcer) association has formed. However, when a second stimulus (SD2) was presented during a 10-s delay to reinforcement,

the rate of responding to SD1 was greatly reduced. In short, the presentation of a better predictor of food (SD2) functionally reduced the association between SD1 and reinforcement. Interestingly, many assumed that the observed blocking effect was due to interference by a Pavlovian association between SD2 and food. However, in a replication of the first study, Williams (1978) showed that by simply eliminating SD2 after being established as the blocking agent, the blocking effect was eliminated; in other words, the association between SD1, the response, and the reinforcer was still intact. In 1999, Williams further demonstrated that where the SD2 signal occurs in the delay between the SD1 response and the reinforcer determines whether SD2 serves to enhance responding to SD1 or serves to block the SD1 response-reinforcer association. Increasing the delay to 30 s allowed for the presentation of SD2 either the first 5 s or the last 5 s of the delay. From a traditional operant perspective, SD2 should function as a conditioned reinforcer in both cases. But the data showed that the nature of the SD1 response-reinforcer association changed as a result of the SD2 temporal placement. Early placement led to a marked enhancement of responding – allowing SD2 to function as a conditioned reinforcer by marking responses to SD1. However, late placement of SD2 functionally blocked the ability to learn the contingency between SD1 responses and reinforcement altogether. These findings suggest that operant associations (specifically with regard to operant blocking) are qualitatively different from the associations formed in Pavlovian blocking, despite having some analogous effects on learning.

### **From Associationism to Connectionism to Cognitive Neuroscience**

Modern associationism encompasses a variety of viewpoints and theories that attempt to explain complex phenomena such as blocking, overshadowing, and latent learning. Associative models, such as the Rescorla-Wagner (1972) model, the MacKintosh (1975) model, and the Pearce-Hall (1980) model, have dominated these

efforts (for a detailed comparison of these associative models, see Wasserman and Miller 1997). With the advent of the modern cognitive revolution, a flood of connectionist and physiological theories, designed to explain how these associations are formed, have resulted in research positing theoretical, cerebral, and neural structures responsible for simple learning and more complex thinking and reasoning (for examples see Abraham et al. 1972; Acevedes-Piña and Quinn 1979; Benowitz 1972).

Wasserman and Miller (1997) provided a detailed account of the field of associative learning through the 1990s. They highlighted the importance of classical conditioning in future progress toward a coherent and complete understanding of human cognition. They invited neuroscientists and cognitive scientists to join forces with experimental psychologists in an interdisciplinary effort to understand and explain the complexities of associations and mental behavior. Although a comprehensive review of connectionism and neuroscience research related to associative learning is beyond the scope of this review, a brief summary and a few seminal examples may suffice to illustrate the approaches.

### **Associations, Connectionism, Neuroscience, and the Single Cell**

By the 1990s, the synthesis of mathematics, computer science, and associative learning came to the forefront of integrative science. Mathematical algorithms, combined with the concept of the “hardware” of the brain, led to complex computational theories designed to account for how the brain manages the associations responsible for a wide array of behaviors. Although not a new idea (Hebb 1949), the technological advances of the late twentieth century allowed for new efforts to connect associative learning to the biology of the brain.

**Connectionism** attempts to explain mental behavior using mathematical models called neural networks. The approach blended Hebb’s (1949) proposal that the connection between two neurons is strengthened whenever both are activated at the

same time with the concept of the association. The result was a division of computer programming that would focus on simulating the development of associations with an emphasis on higher mental behaviors like memory, language, and reasoning. The fundamentals of connectionism are based on interconnected networks of neural “units.” Using a series of algorithms, connections between neural units are strengthened (Waskan 2010).

According to a connectionist perspective, mental states are described as a pattern of activation values. Memories or thoughts are created and modified by changing the strength of specific neural connections. Neural units theoretically represent neurons or clusters of neurons; activations can be thought of as neural firings. Being highly mathematical in nature, these theories lack grammar and symbols, making them applicable to non-verbal learning in animal populations (Kehoe 1989). As activations occur between neural units, connections develop and associations are formed and strengthened. Commonalities between connectionist mechanisms and Pavlovian associations have been drawn and discussed (Kehoe 1989). In a simple example, Pearce (2002) contrasts his own connectionist theory with the Rescorla-Wagner model.

*Limitations.* A number of limitations to the connectionist approach have been noted. First, only as computer technologies advance does connectionism follow. The models are inextricably linked to the current state and underlying limits of computing technology at any given time. For example, as early digital serial-processing computers were replaced by the invention of parallel distributed processing systems, changes to the connectionist models necessarily followed. With the advent of the Internet, and other forms of distributive knowledge, connectionism is merging with a new “connectivism” that includes unit connections with nonhuman appliances and non-biological sources of information (for a review, see Goldie 2016).

A second criticism of the associationist/connectionist approach points to its lack of confirmatory evidence with biological systems. Connectionist models are purely mathematical and theoretical; confirmatory evidence is often produced through computer simulations rather

than through data fitting with real animal or human data. Kehoe (1989) provided some of the earliest attempts to fit preexisting classical conditioning acquisition curves using a connectionist model. However, connectionism as a field has moved more in the direction of linguistics and human language (Ellis 1998), leaving the advancement of connectionist models of classical conditioning to only a few researchers (Gingrich and Byrne 1987; Kemp and Eckerman 2001; Mignault and Marley 1997). In 1991, Commons, Grossberg, and Staddon edited a volume on the current state of network modeling, conditioning, and action. Baxter et al. (1991) reviewed connectionist networks and elements that simulate both classical and operant conditioning processes and phenomena. Specifically, they provide a detailed review of work related to single adaptive elements, small empirically derived neural networks, and tests of simulations. But, at the time, little experimental data was available.

Since the 1980s, the biological science of associationism has rapidly come to the forefront of classical conditioning research. Advancing neural technologies have opened the door to a sophisticated behavior neuroscience.

## Associations and Neuroscience

The initial emphasis on large neocortical structures led to a better understanding of the regulatory importance of the hippocampus in association-based learning and performance.

In 1975, Berger, Alger, and Thompson reported substantial increase in hippocampus activity in rabbits undergoing either paired (CS+/US+) or unpaired (CS+ only or US+ only) trials. The CS+ stimulus was a tone; the US was a puff of air. They measured anticipatory blinking of the nictitating membrane as the dependent variable. Marked increases in blinking during the CS+ test condition were noted for the CS+/US+ condition only. Hippocampal responding developed within a very few training trials. The authors suggested that, at the time, this hippocampal response was perhaps the earliest cerebellar indicator of associative learning. Berger et al. (1976) later suggested

that pyramidal neurons are the cell type that accounts for the increases in hippocampal firings. In 1984, Berger demonstrated that long-term potentiation of the hippocampus prior to training increased the rate of CR acquisition. Over the next decade, the search to identify other brain areas involved in associative learning was well underway.

By the early 2000s, a fairly clear picture of the brain structures involved in classical fear conditioning was established. Christian and Thompson (2003) provide a review of the various neural substrates implicated in rabbit eyeblink conditioning, including the hippocampus, the frontal cortex, the amygdala, the motor cortex, as well as specific pathways related to the US, CS, UR, and CR. But the desire to understand the underlying neural mechanisms responsible for the formation of associations necessarily invited a greater interplay between the fields of learning, experimental psychology, and neuroscience. As the foundation for this new neuroscience movement, associative learning was accepted as an ideal paradigm for studying the how the physical brain accomplishes sophisticated behaviors like classical conditioning, associative memory, and the generalization of associations. Throughout the late twentieth and into the early part of the twenty-first century, the focus on the underlying neural substrates of learning has continued to increase.

## Single-Cell Associative Learning

In one of the earliest behavioral demonstrations of classical conditioning in an invertebrate, Kandel and Schwartz (1982) showed that weak, tactile stimulation of the siphon or mantle of the marine snail *Aplysia* (CS) paired with electrical shocks to the animal's tail (US) results in prolonged responsiveness to additional tactile stimulation in the absence of the US: evidence of classical conditioning.

By 1983, Walters and Byrne had proposed a cellular/neural mechanism for appetitive associative learning based on the associative conditioning of individual sensory neurons involved in the same tail withdrawal reflex of the *Aplysia*. They applied a cellular analog of Hebb's (1949)

classical conditioning using a dissected split-foot preparation with two intact sensory neurons and one motor neuron from an *Aplysia* (see Fig. 5). They applied a series of nine suprathreshold depolarizing pulses to the sensory neurons as the CS+ stimulus and an electrical shock to the motor neuron as the US stimulus. In the "paired condition," CS+ pulses to one sensory neuron were paired with the US shocks to the motor neuron; in the "unpaired condition," CS+ and US stimuli were presented equally often but never together. A third control condition involved US stimulation only. Firing on the motor neuron was measured during CS-only tests. Results showed the synaptic connection between the CS+ sensory neuron and the motor neuron in the paired condition was significantly strengthened relative to the other two conditions.

Subsequent studies (for a brief review, see Glanzman 1995) suggest that this form of cellular classical conditioning is mediated, not only by a presynaptic cellular mechanism but by postsynaptic and peripheral synaptic mechanisms as well. Glanzman's continued research with classical conditioning has led to a better understanding of the mechanisms of associative learning and synaptic plasticity in invertebrates and vertebrates (Roberts and Glanzman 2003).

Following up on previous work, Watanabe and Mizunami (2007) extended previous behavioral findings to neural measurements of classically conditioned salivation in surgically altered cockroaches. They tested sensitivity to appetitive odor (CS+) conditioning using exposed salivary duct nerves that consist of two neurons with large-diameter axons (SN1 and SN2) with cell bodies in the suboesophageal ganglion (SON), as well as several smaller-diameter axons. Before conditioning, the neurons respond similarly to vanilla and peppermint. After only five classical conditioning trials with vanilla and saline (V-) and peppermint and sucrose (P+), both the SN1 and SN2 exhibited significantly greater neural responses to peppermint alone than to vanilla alone. In fact, post-training responses to vanilla alone approximated responses to peppermint before training although the animals had previously shown a natural preference for vanilla over peppermint.

**Associative Mechanisms, Fig. 5** A schematic of the typical experimental split-foot preparations in *Aplysia* (as per Carew et al. 1984). The tail nerve (posterior pedal nerve – P9) was used to deliver US stimulation and to record motor nerve firings. One sensory neuron (SN) received paired CS+/US stimulation; another SN received unpaired CS+/US stimulation. Reprinted with

permission from *The Journal of Neuroscience*. (The typical experimental split-foot preparation in *Aplysia* (as per Carew et al. 1984). Anyone may reprint original *JNeurosci* material without requesting permission. A full journal reference and link to the version of record, where appropriate, must be included. <https://www.jneurosci.org/content/rights-permissions>)

Mizumani and his colleagues have gone on to use crickets to investigate the role of octopaminergic and dopaminergic neurons in mediating reward and punishment signals in insect visual learning (Unoki et al. 2006), as well as in appetitive and aversive memory (Mizunami et al. 2009). He has also identified context-dependent discrimination learning at the neural level in cockroaches using visual context

and olfactory and gustatory cues (Sato Matsumoto et al. 2012).

Although we do see gradual progress in the mapping of brain structures and neural stimulation associated with fear conditioning in mammalian brains (Maren 2001), Mazunami has suggested that cockroach neurons may serve as a valuable model for studying the cellular mechanisms of

associative learning due to their simple nature. In mammals, even reflexive responses like salivation are much more complex in comparison. Neuroscience research with mammals remains largely at the structural level. But the current progress in understanding the underlying neural mechanisms of associative conditioning appears to be led (at least for now) by studies with insects such as fruit flies, *Drosophila* (Berry et al. 2008; Davis 2005; Heisenberg 2003; Honjo and Furukubo-Tokunaga 2009; Schroll et al. 2006; Schwaerzel et al. 2003; Thum et al. 2007), honeybees (Farooqui et al. 2003; Giurfa 2007; Hammer and Menzel 1998; Menzel 2001), and moths (Dacks et al. 2005; Daly et al. 2004).

## Assortative Mating

Alice Baniel  
Institute for Advanced Study in Toulouse,  
Toulouse, France

## Synonyms

Nonrandom mating; Assortative pairing; Assortment; Homogamy; Assortative mating; Disassortative mating; Heterogamy

## Definition

Assortative mating is defined as a pattern of non-random mating, where there is a correlation (positive or negative) between male and female genotypes and/or phenotypes across mating pairs. Positive assortative mating (also called

homogamy) implies a tendency to mate with genetically or phenotypically similar individuals. Conversely, negative assortative mating (also called heterogamy or disassortative mating) implies a tendency to mate with genotypically or phenotypically dissimilar traits. In the speciation literature, assortative mating is considered as a mechanism that drives reproductive isolation within a diverging population or between distinct species.

## Introduction

An important focus in the field of sexual selection over the past decade has been to understand how and why animals choose their mates. In some cases, mate choice has been found to rely on absolute criteria: individuals share the same preferences and choose a mate who offers them the best direct benefits to increase their survival or fecundity (e.g., high-quality territory, nuptial gifts), or the best indirect genetic benefits to increase offspring's fitness (often reflected by ornament-based choice). In other cases, mate choice has been found to rely on relative criteria, where individual preferences vary according to their own genes or phenotype. Assortative mating represents a process of mate choice based on relative criteria. It is a mating pattern commonly observed in animals (Jiang et al. 2013) and has attracted interest from both empiricists and theoreticians due to its importance in population genetics and speciation.

In animals, positive assortative mating between breeding pairs has been found for numerous phenotypic traits, including morphological traits (body size, coloration, ornament), physiological traits (age, pheromone response), or behavioral traits (diet, personality), and across many taxa, including insects, crustaceans, gastropods, amphibians, fish, birds, reptiles, and mammals (see Jiang et al. 2013 for a review). The traits under assortative mating often – but not always – reflect individual phenotypic condition and/or genetic quality. For instance, in wild American goldfinches *Carduelis tristis*, the carotenoid-based yellow plumage colors of males and females reflect individual quality and are

positively correlated across breeding pairs (MacDougall and Montgomerie 2003). Assortative mating has been particularly well studied in humans. Many studies have found that men and women tend to mate with someone who is similar to themselves, on one or several phenotypic traits, including physical appearance (facial traits, eye and hair color, body height), socio-economic status, education, age, religion, or personality traits (see Štěrbová and Valentová 2012 for a review).

In contrast, negative assortative mating on phenotypic traits seems to be comparatively scarce in nature (Jiang et al. 2013; Thiessen and Gregg 1980). It has been reported, for example, in some birds where two color morphs coexist and where individuals prefer to mate with the opposite morph (Jiang et al. 2013). Inbreeding avoidance is often observed in animals and may or may not represent disassortative mating (avoidance of close kin does not specifically require choosing the opposite trait in mates, but just a different trait from self). At the genetic level, most examples of disassortative mating come from studies of the Major Histocompatibility Complex (MHC). The MHC is a highly polymorphic cluster of genes involved in immune function and pathogens recognition. As MHC alleles are expressed codominantly, choosing a dissimilar mate at MHC might increase the likelihood of obtaining a genetically diverse offspring at MHC genes, which in turn allows the offspring's immune system to recognize and fight a broader array of pathogens. Females of many species have been found to pair preferentially with MHC-dissimilar males (Piertney and Oliver 2006), including in humans (Havlicek and Roberts 2009). However, MHC-disassortative mate choice is not always observed, and in some cases mate choice for MHC-similar mates is reported within the same species.

It is important to distinguish between assortative mating *pattern* and *preference*, because the mating pattern of a population is not necessarily a direct consequence of the mating preferences of individuals (see discussion below). To test empirically for a *pattern* of associative mating in a given population, one needs to calculate the correlation between the values of homologous phenotypic or genotypic trait

(s) across breeding pairs. This correlation coefficient gives a measure of the strength and direction of assortative mating. To test for an assortative mating *preference*, animal studies investigate female or male mate choice, for example, in a two-way apparatus where the focal individual can choose between a homotypic (similar for a given trait) and heterotypic mate or observe true mating preferences in controlled experimental design (Egger et al. 2008). In human studies, raters are typically asked to assess the attractiveness of composite or real faces or bodies that are similar or different to themselves (Bovet et al. 2012) or match unknown partners' faces (Bereczkei et al. 2004).

### Which Mechanisms Can Generate Assortative Mating?

Whereas patterns of assortative mating are often observed, the underlying mechanisms that cause them are difficult to understand and disentangle (Jiang et al. 2013). A large number of different processes can lead to assortment. Assortative mating preferences (where one or both sexes show an active preference for similar or dissimilar partners) can evolve adaptively in some cases, under the action of sexual selection. In other cases, assortative mating patterns can be generated by nonadaptive processes.

#### Adaptive Hypotheses

Pairing with genetically similar or dissimilar individuals can be adaptive because it increases the fitness of a pair's offspring. Disruptive selection (individuals with extreme values of a trait have higher fitness) will favor the evolution of positive assortative mating to avoid producing less fit intermediate offspring (Dieckmann and Doebeli 1999; Kirkpatrick and Ravigné 2002; Kondrashov and Shpak 1998). Many insects and birds mate assortatively on the basis of similar color patterns to avoid producing offspring with maladaptive patterns that would, for instance, make it more easily detected by predators or less attractive as a mate (Jiang et al. 2013). In contrast, stabilizing selection (individuals with intermediate values of a trait have higher fitness) will favor

the evolution of negative assortment to reduce the production of less fit extreme offspring.

Assortative mating can evolve in response to inbreeding or outbreeding depression for similar reasons. Mating with a partner of relatively similar genetic background might be evolutionarily advantageous because it decreases outbreeding depression in offspring. Outbreeding induces a fitness cost in several species, either because of the disruption of locally co-adapted gene complexes in offspring, underdominance (selection against the heterozygotes), or epistatic interactions (Epinat and Lenormand 2009). Conversely, negative assortative mating is expected to evolve to avoid inbreeding depression, which increases the risk of expression of recessive deleterious alleles in offspring (Epinat and Lenormand 2009). For example, avoidance of close kin as mating partners (and thus inbreeding depression) is known to be enforced in several species by a biological mechanism (called the Westermarck effect), where individuals develop a strong sexual aversion toward co-residents during infancy, generally close kin members (Marcinkowska et al. 2013).

Given the severe negative consequences of inbreeding, it is surprising that positive assortative mating is more frequently observed than negative assortative mating. In fact, the "optimal outbreeding theory" posits that individuals have evolved to choose a mate with some degree of relatedness, representing the optimal balance between inbreeding and outbreeding, as an adaptive compromise between these opposing selection pressures (Bateson 1983). In short, individuals should mate with partners who are relatively genetically similar, but not close relatives. Positive assortative mating may thus be more often selected to avoid outbreeding depression, given that inbreeding is already prevented by other biological (Westermarck effect) or social mechanisms (such as incest taboos in humans, Bovet et al. 2012). Consistent with this hypothesis, a growing body of literature shows that individuals prefer an optimally – rather than maximally – dissimilar partner at MHC genes, as excessive MHC diversity may prevent an efficient immune response or disrupt locally adapted allelic combinations (Piertney and Oliver 2006).

Several other hypotheses have been proposed to explain the prevalence of positive assortative mating preferences. First, a preference for self-resembling individuals may be adaptive because, as suggested by kin selection theory, cooperation and altruism between potential mating partners are promoted when they share a high number of genes (Thiessen and Gregg 1980). Second, positive assortative mating may be adaptive because it increases the number of shared genes between parents and the probability to transfer own genes in offspring (Genetic similarity theory: Rushton 1989). These two hypotheses nonetheless require that assortative mating is based on a large number of genetically heritable traits and that phenotypic cues of assortative mating are a reliable measure of genetic proximity. Third, selection for positive assortative mating could also be based on non-genetic, but fitness-maximizing, mechanisms. For instance, behavioral similarity between partners may promote within-pair compatibility, via a better coordination or share of parental investment, and results in higher reproductive success. In zebra finches, it has been found that offspring survival during the rearing period increases with behavioral similarity between parents (Ihle et al. 2015). In humans, homogamy seems to enhance marital stability and fertility (Štěrbová and Valentová 2012).

Regardless of the type of selection involved, assortment can be the consequence of mutual mate choice from both males and females or occur through the mating behavior of one sex only. In species with bi-parental care, mutual mate choice based on quality-indicating ornament(s) is frequently observed, since the evolution of discriminating males and females for partners with equal investment is adaptive to both sexes (MacDougall and Montgomerie 2003). In contrast, only female mate preference for assortative mating on male nuptial coloration seems responsible for the rapid diversification of cichlids (Egger et al. 2008).

### Nonadaptive Hypotheses

Assortative mating may not always be adaptive, but arise as an incidental consequence of other aspects of pair formation (Crespi 1989).

The first mechanism is temporal segregation (or allochronic isolation). In phytophagous insects that use several host plants which fruit or bud at different times, mating on different host plants can lead to allochronic isolation of mating pairs (Groman and Pellmyr 2000). Age-assortment is often generated by temporal segregation between generations or by age-specific access to reproduction.

Spatial segregation among phenotypes is a second mechanism that could generate incidental positive assortment: when there is covariation between a phenotype and the habitat in which individuals mate, the probability of encountering phenotypically similar mates increases. This can occur when individuals with similar phenotypes have similar habitat preferences. For instance, in insects that mate on their host plants, consistent individual preferences for a specific host lead to spatial segregation of breeding pairs (Feder et al. 1994; Malausa et al. 2005). In several arthropods, size-assortment arises because individuals of similar sizes aggregate in the same patches (because size determines resource or substrate use) (Crespi 1989). By extension, positive assortative mating in humans may often be a consequence of the fact that individuals who are similar in socio-economic status, interests, or personality are more likely to meet and thus mate with each other (Štěrbová and Valentová 2012). Covariation between phenotype and habitat can also occur when there are phenotypic (or genotypic) clines in the spatial distribution of a population, due, for instance, to adaptation to an environmental gradient. In animals, assortative mating arising as an incidental outcome of temporal and spatial segregation may be an important process facilitating sympatric speciation (see paragraph below on the evolutionary consequences of assortative mating).

Third, mate similarity can arise as a by-product of intrasexual competition for mate and intersexual conflict (Crespi 1989). Under strong intrasexual mating competition, individuals with high-quality (or attractive) phenotypes will choose their preferred mate from the available pool first, leaving low-quality (or unattractive) individuals to pair with those who remain unpaired, causing positive assortment despite the

fact that all individuals prefer mates belonging to the same category. In many invertebrates, both female fecundity and male competitive ability are positively correlated with body size (Crespi 1989). Thus, large competitive males choose large, highly fecund females, whereas the losers have to accept smaller and less fecund females, resulting in positive size-assortative mating (Harari et al. 1999; McLain and Boromisa 1987). In the case of intersexual conflict, larger females are better able to resist mating attempts from large, aggressive males, and only the largest males are able to mate with them, again resulting in positive assortment.

Fourth, assortative mating can be generated by mechanical constraints during copulation that prevent random mating. For example, copulation can be physically difficult between males and females of different size, because of a lack of coincidence in anatomical parts, resulting in size-assortative mating (Crespi 1989).

Fifth, a higher similarity between breeding pairs compared to nonbreeding pairs can simply arise from the behavior of the partners converging over time (“postpairing convergence”). In the convict cichlid *Amatitlania siquia*, behavioral similarity between mismatched partners increases after pairing, because one partner adjusts their behavior to the other (Laubu et al. 2016).

Thus, the observed mating *pattern* of a population is not necessarily a direct consequence of the mating *preferences* of individuals. Patterns of assortative mating can be determined by both the mating preferences of individuals and many possible processes of pair formation (Jiang et al. 2013). As a result it is impossible to make definitive statements about the assortative mating preferences of individuals simply by observing the mating pattern of a population. Accordingly, it is impossible to predict the mating pattern of a population from the mating preferences of its constituent individuals. Studies thus need to address both mating preferences and pattern concomitantly.

### Variation in the Strength of Assortative Mating

The intensity of both adaptive and incidental assortative mating should not be viewed as

constant in a population or species, but rather is likely to vary across time according to the different selection pressures at play (Jiang et al. 2013). If assortative mating evolves as a response to inbreeding and outbreeding depression in a way to optimize the degree of relatedness among mating partners, inbred populations should exhibit disassortative preferences and outbred populations assortative preferences. This may explain the contradictory results of MHC-biased mating preferences across different human populations (see Havlicek and Roberts 2009 for a review).

Similarly, if assortative mating arises as an incidental outcome of competition for mates, variation in the intensity of intrasexual competition and/or intersexual conflict within or across population(s) may determine the intensity of assortment (Harari et al. 1999; McLain and Boromisa 1987). Population density, the operational sex ratio, and ecological conditions are known to influence the intensity of both intra- and intersexual competition and can thus affect assortment. For example, positive assortative mating increases with population density in milkweed longhorn beetle *Tetraopes tetraophthalmus* because large males are more likely to interfere when small males copulate with large females at high density (McLain and Boromisa 1987).

A recent meta-analysis has emphasized that the frequency and strength of assortment differ significantly among taxonomic groups, among populations, and among different traits for the same population (Jiang et al. 2013). Quantifying the direction and strength of assortative mating can shed light on the nature of the underlying mechanisms (i.e., adaptive versus incidental assortative mating) by testing whether it covaries with the intensity of competition.

### What Are the Phenotypic Cues of Assortative Mating Preferences?

Several mutually nonexclusive proximate mechanisms have been proposed to explain how individuals can detect genetic and/or phenotypic similarities in unfamiliar potential mates.

First, assortative mating preferences can be mediated by self-referent phenotype matching, where individuals compare phenotypes of unfamiliar individuals with their own phenotypes and choose those who are similar to themselves (Hauber and Sherman 2001). Animals have been shown to detect similarity between their own phenotypes and those of unfamiliar individuals through visual cues, odors, vocalizations, or environmental predictors (Hauber and Sherman 2001). The internal representation necessary to do self-referencing might be learned and/or unlearned (environmentally or genetically determined, Hauber and Sherman 2001). In the latter case, mating preferences are genetically determined and in linkage disequilibrium with loci coding for phenotypic traits used in assortment. In *Heliiconius* butterflies, for instance, hybrid color morphs inherit mating preferences from both parental morphs and mate assortatively with morphs of their own color pattern (Melo et al. 2009).

Second, assortative mating can be mediated by sexual imprinting, a nongenetic mechanism where individuals acquire mate-choice criteria during development by using their opposite-sex parent as the template (Hauber and Sherman 2001). Sexual imprinting can either be positive, when individuals shape a preference for their parents' characteristics (Bereczkei et al. 2004), or negative, when individuals develop a sexual aversion to individuals similar to their parents (Marcinkowska et al. 2013). The learning period is thought to be confined to an early sensitive period when only closely related individuals are likely to be present and will shape mating preferences until adulthood. Consistent with this hypothesis, cross-fostering experiments in birds and mammals (where offspring are transferred to a non-natal family) have shown that males prefer sexual partners who are similar to the female who has reared them (see Hauber and Sherman 2001 for a review). Sexual-imprinting-like mechanisms have been argued to influence human mate choice too, with studies reporting facial resemblance between a mate and his partners' opposite-sex parent (Bereczkei et al. 2004), but its importance remains debated.

Because offspring are expected to resemble their parents owing to genetic similarity, the resemblance between the mate and the opposite-sex parent may not be caused by sexual imprinting but rather by self-referent phenotype matching. Cross-fostering experiments in animals help to distinguish between those two mechanisms: if the cross-fostered animal shifts its sexual preference towards individuals of the foster phenotype, preferences are likely to be imprinted. The two mechanisms are nonetheless nonmutually exclusive and both seem to exist (Hauber and Sherman 2001).

Regardless of the mechanism involved, individuals can rely on many different phenotypic cues (or a combination of them) to mate assortatively. Individuals can rely on visual cues, such as plumage coloration in birds (MacDougall and Montgomerie 2003) or morph coloration in butterflies and fishes (Egger et al. 2008; Melo et al. 2009). In birds, assortative mating is often mediated by vocalizations during courtship (Clayton 1990). Assortative mating can also be mediated via pheromonal communication in insects or body odors in mammals.

## What Are the Evolutionary Consequences of Assortative Mating?

Assortative mating has several important evolutionary consequences on the genetic structure of populations and on the speciation process.

### Assortative Mating and Population Genetics

When genetically similar individuals mate, offspring are more likely to receive two copies of the same allele at the loci coding for the trait(s) used in assortment. As a result, positive assortment increases homozygosity within genomes (Crow and Felsenstein 1968; Thiessen and Gregg 1980). Assortative mating will nonetheless not lead to complete homozygosity, as would inbreeding, because it affects only the loci coding for the trait(s) used in assortment.

Positive assortative mating also alters the probability that a particular allele will be associated with other alleles, and consequently promotes

linkage disequilibrium between loci (in particular between the loci coding for mating preferences and the loci coding for the traits under assortment). This increase in homozygosity and linkage disequilibrium in genomes resulting from positive assortative mating in turn (1) inflates the genetic variance of quantitative traits by favoring extreme types and (2) increases heritability between parents and offspring (Crow and Felsenstein 1968). The variance-enhancing effect of assortative mating can be understood in a simple one-locus system. If homozygotes mate assortatively ( $AA \times AA$  and  $aa \times aa$ ), they only produce more of their own type, whereas if heterozygotes mate ( $Aa \times Aa$ ) they will leave only half as many of their type in the next generation: the extreme phenotypes are favored at the expenses of intermediate ones, causing an increase in the genetic variance. Note that positive assortative mating by itself does not affect allele frequencies of a population (individual allele frequencies do not change and no alleles are gained or lost from the population). It affects only genotype frequencies, by restructuring the allelic composition of individuals and creating deviation from Hardy-Weinberg disequilibrium within loci (Crow and Felsenstein 1968).

The increase in genetic variance due to positive assortative mating (1) increases the response to selection of populations and the rate of evolutionary change (since more genetic variation leads to quicker and larger genetic shift in the value of the trait under selection) and (2) might be an important mechanism that maintains variance in phenotypic traits, despite the variance-eroding effects of other forms of sexual selection – i.e., choice for absolute, rather than relative cues (Arnqvist 2011).

In contrast, negative assortative mating increases heterozygosity within genomes, maintains polymorphism, prevents allelic fixation, and facilitates the maintenance of sexually antagonistic variation (Crow and Felsenstein 1968; Thiessen and Gregg 1980).

### Assortative Mating and Speciation

Assortative mating plays a key role in speciation in two contexts. First, it can be a mechanism of

prezygotic isolation that reduces gene flow between phenotypically divergent populations and causes a population to split into two, resulting in sympatric speciation where two daughter species arise without geographical isolation of the mother population (Kirkpatrick and Ravigné 2002). Female and/or male preference for assortative mating is thought to be responsible for the rapid speciation of many species, as illustrated in cichlids (Egger et al. 2008). Second, assortative mating can participate to maintain the genetic isolation of two populations that come into secondary contact and prevent them from merging back into a single population (Kirkpatrick and Ravigné 2002; Kondrashov and Shpak 1998). For example, two subspecies of Indonesian zebra finches living in sympatry were found to exhibit strong assortative mating on plumage coloration and song to discriminate and mate with members of their own subspecies, leading to the maintenance of reproductive isolation (Clayton 1990).

In models of speciation, reproductive isolation via positive assortative mating evolves in response to disruptive selection, to reduce the production of less fit phenotypically intermediate offspring (Kirkpatrick and Ravigné 2002). Conversely, stabilizing selection favors the evolution of negative assortative mating, to reduce the production of less fit phenotypic extremes (Kirkpatrick and Ravigné 2002; Kondrashov and Shpak 1998). However, theoretical models have shown that positive assortative mating does not always lead to speciation even in a population under disruptive selection. In particular, if the loci coding for the phenotypic traits that are used for assortative mating act independently from the loci that are under disruptive selection, recombination will break up associations between loci affecting survival and those determining mate choice, so that there is a low probability of speciation (Kirkpatrick and Ravigné 2002). If, however, assortative mating is pleiotropically controlled by the same loci that are under disruptive selection (pleiotropy describes the fact that a single gene influences multiple phenotypic traits – here mate choice and survival), antagonism between recombination and selection is reduced so that initial assortative mating can be enhanced

by reinforcement, and speciation becomes much more likely (Dieckmann and Doebeli 1999; Kirkpatrick and Ravigné 2002). Several theoretical models have shown that speciation can happen even in the absence of pleiotropy (Dieckmann and Doebeli 1999; Kondrashov and Shpak 1998), but it remains unclear whether the assumptions of these models are met in nature. Overall, the most favorable situation for sympatric speciation is when assortative mating is based on a trait directly under disruptive selection (Kirkpatrick and Ravigné 2002). Those traits have been called “magic traits” by some researchers that questioned the generality of this mechanism in generating sympatric speciation. However, there are some clear examples of ecological divergence directly causing assortative mating, such as when habitat preferences lead to spatial segregation of mating pairs (Feder et al. 1994; Malausa et al. 2005).

Positive assortative mating is, however, likely to trigger costs that may potentially delay or prevent speciation processes (Otto et al. 2008). Potential costs of assortative mating include the energetic costs of searching for compatible mates (rare phenotypes are less likely to find mates than are common ones), the risk of rejecting all potential mates and remain unmated, and the costs of mechanisms that allow perception of similarity in potential mates. However, the costs of assortative mating may rarely hinder the evolution of reproductive isolation, unless they are sufficiently high (Otto et al. 2008).

## Conclusion

Assortative mating has attracted the attention of evolutionary biologists because it relies on relative criteria and because it can influence the genetic structure of a population and the rate of evolutionary changes and promote speciation in some circumstances. Determining the causes of assortative mating has nonetheless proven difficult and studies that clearly distinguish between alternative hypotheses of assortment are lacking. In both animals and humans, assortative mating is predominantly positive (Jiang et al. 2013). Since disruptive selection (favoring positive assortative

mating) and stabilizing selection (favoring disassortative mating) on phenotypic traits occur at similar frequency and strength in natural populations, positive and negative assortment should occur at about the same frequency. Therefore, it has been suggested that disruptive or stabilizing selection is not the primary forces driving the evolution of assortative mating (Jiang et al. 2013). The second adaptive explanation of assortative mating involving direct selection favoring trait-matched breeding pairs might explain the asymmetry between positive and negative assortative mating, although this process is not widely documented (Jiang et al. 2013). Clearly, assortative mating evolves adaptively in some cases, but nonadaptive processes generating positive assortative mating patterns appear important in explaining its prevalence. Future studies that distinguish between alternative hypotheses of mate assortment are needed to elucidate this question.

Law of independent assortment

Definition

When alleles at a locus separate during gamete formation, their assortment is independent of the separation of alleles at other loci.

Introduction

Independent assortment is widely known as the second law of Mendel which was proposed in 1865 during his study of genetics in pea plant. This principle was formulated after the law of segregation had been described. According to the law of segregation, the alleles for a trait separate during gamete formation, and one allele is passed on to each of the gamete. The law of segregation was discovered through performing monohybrid crosses (using plants differing only in a single trait) and also described the concept of

dominant and recessive traits. Four important inferences were drawn from monohybrid crosses:

- Two alleles exist for each trait.
- These alleles separate during gamete formation, and one allele goes into each gamete.
- There are dominant and recessive alleles. Dominant alleles reappear in F1 generation, whereas recessive alleles disappear or are suppressed in F1 generation.
- The two alleles separate with equal probability into gametes.

Dihybrid Cross

Mendel crossed varieties of peas that differed in only two characteristics. Such crosses are referred as dihybrid crosses, and always a ratio of 9:3:3:1 was obtained in the F2 generation (Fig. 1). This

**Assortment, Fig. 1** Mendel’s dihybrid crosses explaining law of independent assortment (Figure adapted and modified from Klug et al. (2012))

ratio can only be obtained due to the principle of independent assortment since alleles at different loci separate independently of each other. In F1 generation of a dihybrid cross, offsprings have heterozygous genotypes (RrYy in Fig. 1). When F1 is fertilized to produce F2 generation, the independent assortment of these alleles becomes evident. As shown in Fig. 1, R, r, Y, and y can assort independently to produce four gametes with genotypes (RY, Ry, rY, and ry) in equal proportions. Two new allelic combinations (Ry and rY) are also obtained as a result of independent assortment.

## Independent Assortment and Meiosis

Independent assortment of genes occurs during meiosis in eukaryotes. Each pair of homologous chromosome separates independently of all other pairs in anaphase I of meiosis. Genes located on different homologs will therefore assort independently. However, if the genes are located on the same chromosome, they may or may not assort independently. Genes that are located apart might undergo recombination during meiosis. Recombination allows scrambling of maternal and paternal genes to produce new combinations of genes in the offspring. In effect, recombination increases the chances of independent assortment of genes present on the same chromosome.

## Linked Genes: Inconsistency of Independent Assortment

When genes are located close together on the chromosome, they are said to be linked. So, the alleles are inherited together as a unit more frequently than expected, and this phenomenon is referred to as genetic linkage. The strength of linkage between two genes depends on the distance between them on the chromosome. Linked genes were first observed and reported by William Bateson, Edith Rebecca Saunders, and Reginald C Punnett in 1905. They noted that traits for flower color and pollen shape in sweet pea plants appeared to be linked together (Pierce 2012). Later, work of T.H. Morgan and his student on

*Drosophila* also reported gene pairs that did not segregate randomly according to Mendelian principle, instead tended to be inherited together.

## Conclusion

Mendelian principle of independent assortment based on dihybrid crosses explains that all possible combinations of alleles can be formed during gamete formation with equal probability. However, linked genes are an exception to this principle and are more than frequently inherited together.

## Attachment

Elizabeth K. Wood and J. Dee Higley  
Brigham Young University, Provo, UT, USA

## Synonyms

[Arousal regulation](#); [Bonding](#); [Mother-infant bonding](#)

## Definition

Attachment in animals can be defined primarily as the psychological bond between a mother and an infant, although there are some species in which an infant is bonded to its father. The strength of the attachment bond is measured by the degree to which the infant attempts to remain in proximity to the caregiver and the relative extremity of distress experienced by one or both of the members of the bond when access is restricted. Attachment quality is further assessed through the degree that an infant's arousal is reduced by the presence of their mother. The strength and quality of the attachment bond impacts the long-term trajectory of development, including future peer and romantic attachment relationships.

## Introduction

A child seeks his attachment-figure when he is tired, hungry, ill, or alarmed and also when he is uncertain of that figure's whereabouts; when the attachment-figure is found he wants to remain in proximity to him or her and may want also to be held or cuddled. By contrast, a child seeks a playmate when he is in good spirits and confident of the whereabouts of his attachment-figure; when the playmate is found, moreover, the child wants to engage in playful interaction with him or her. (John Bowlby 1969, p. 307)

In altricial species, natural selection has favored processes that keep infants close to their caregiver, most often their mothers who provide protection and assure nutrition, warmth, and, ultimately, survival. Lorenz' studies on imprinting illustrate this process, with hatchlings inherently following the most salient, moving individual they see after emerging from their egg (1937). In primates and other species with larger brains and extended periods of development, mechanisms that keep infants close to their caregiver assure that the infant has sufficient time, as well as a "teacher", to learn the behaviors necessary to survive and successfully exploit their environment. Attachment between an infant and its primary caregiver involves a component of trust, wherein the infant trusts that the caregiver will consistently respond

to its needs, providing psychological and physiological support. Rooted in maternally-induced reductions of infant arousal, the mother adjusts her mature and flexible behaviors to meet the needs of her immature infant, facilitating an attachment bond.

That a mother reduces infant arousal via parenting behaviors to promote infant attachment bonds (arousal regulation theory) is grounded in the Yerkes-Dodson Law, proposed in 1908 by Robert Yerkes and John Dodson, which law posits that an optimal level of arousal is preferred for optimal performance (see Fig. 1).

While mothers are mature enough to regulate their own arousal, altricial infants' brains are not equipped to do so due to their immature emotional neural circuitry. For species in which natural selection has favored a prolonged process of post-natal brain development, where synapses are formed and maintained if they are useful and pruned when they lack utility, the brain has a preprogrammed set of expected inputs, known as the experience-expectant brain. Through forming attachment bonds, adequate experiences occur and expected inputs are received, largely by repeatedly "turning off" the anxiety circuit in the brain as the caregiver nurtures and cradles her infant. By responding to her infant's over-arousal, the mother modifies her own behavior, with a goal

**Attachment, Fig. 1** The optimal level of stress is thought to promote optimal performance on a variety of tasks. This theory has also been applied to development, with a caregiver promoting an optimal level of arousal in its infant until the infant can regulate its arousal on their own

of maintaining her infant's arousal at the optimal level. Optimal arousal is most readily achieved when a mother sensitively responds to her infant's needs, individualizing her care. Likewise, when an infant is under-aroused, a mother will engage her infant, allowing it to explore and play, with a goal of increasing its arousal to the optimal level. By so doing, the mother sensitively engages the immature neural pathways in an experience-expectant manner until the infant matures to point that it can adequately regulate its own arousal.

## Rhesus Monkeys

Forming an attachment bond with a caregiver is a primary feature of primates, infants of which are born altricial and have a relatively long period of infancy when compared to raptors, reptiles, and rodents. Studies of rhesus macaques (*Macaca mulatta*) provide critical insights to the development of attachment theory. To date, they are the most-studied primate in terms of mother-infant relationships. Rhesus monkeys live in complex social groups, organized around matriline, with intricate rules requiring emotional regulation and social intelligence to survive. Infants are largely dependent on their mothers for the first few months of life. Indeed, during the first month of life, an infant rhesus monkey spends virtually all of its time in physical contact with its mother. Mothers provide nourishment, physical touch and warmth, protection from threats, as well as psychological comfort (Harlow 1958). As will be discussed, attachment is based on primary reinforcers, which lead to maintaining close proximity with the caregiver and seeking to eliminate negative reinforcers (Bowlby 1969). As the mother fills basic needs and provides sensitive and persistent parenting, an attachment bond forms rapidly between mother and infant. A mother facilitates an environment in which the infant can grow and develop, learning how to survive in a world much larger than itself. Once the attachment bond is formed, the infant insists on being cared for by its mother, as evidenced by its cries

for retrieval by its mother when it is carried away by another female in the troop, persisting until it is reunited with its own mother. For infant primates, only *their* mother will do. Harry Harlow's anecdote about the first surrogate mother is a prime illustration of this exclusivity (1958). When the first surrogate-reared monkey was born (see below), the surrogate body was ready, but the head was not yet designed. In its place was a faceless ball of wood. When the infant was 6-months-old, it was placed with two cloth surrogate mothers who had painted faces. To the surprise of the experimenters, the infant persistently turned the painted heads until it could only view a blank face, despite experimenter efforts to reorient the face. Later, they observed that the infant learned to remove the painted head entirely, rolling it to a corner of the cage.

That an infant rhesus monkey is attached to *their* mother is similarly illustrated in a study utilizing dogs as surrogate mothers (Mason and Kenney 1974). Infants paired with surrogate dogs were tested to determine whether they formed attachment bonds to *their* surrogate dog mother or whether they would respond similarly to any dog. To do so, the monkeys were given a choice of their familiar dog mother surrogate, an unfamiliar dog, or an unfamiliar inanimate surrogate mother. The monkeys choose their familiar dog surrogate almost exclusively, suggesting a unique attachment bond between the infant rhesus and its specific dog surrogate. When only the unfamiliar dog and the unfamiliar surrogate were available, the infant monkeys chose the unfamiliar dog almost exclusively, suggesting that infants seek out a caregiver that possesses certain expected traits, a finding best understood in the context of developmental theory.

In the wild, on the first day following birth, mother rhesus monkeys spend a great deal of time inspecting their infants' genitalia and looking at their infant's face, presumably assessing the sex of the infant and becoming familiar with their infant's characteristics. Early on, when an infant strays from its mother, it is rapidly retrieved and, should it attempt to nurse from another female, it is rejected, at times vigorously (personal

observations, J.D. Higley), perhaps facilitating rapid infant discrimination of its mother from all other females in the group.

As infant rhesus monkeys develop, it is driven by two primary urges, an inherent desire to explore and play, and a secondary desire to remain in close contact with its mother. As an infant's motor skills mature, it will begin to explore its larger environment, using its mother as a secure base (Hinde and Spencer-Booth 1967). The rhesus infant begins by exploring the area immediately around its mother, engaging in social interactions with its peers. About the time that an infant matures to the point that its motor skills allow it to move farther from mother, a fear of strangers emerges, motivating the infant to remain in close proximity. Arousal regulation is a fundamental aspect of this, as infants experiencing low levels of arousal will seek to increase their arousal via peer play. Then, when they become over-aroused by their environment or by feelings of tiredness or hunger, they will return to their mother, she will comfort them, and they will resume their exploration of their environment.

Perhaps the most defining trait of primates, and one that has made rhesus monkeys the second-most prolific primate (humans being the first-most prolific primate), is the capacity of the species to adapt to a variety of settings and environments, living in diverse ecological niches, including the foothills of the Himalayas and the desert lands of Africa. Such adaptation comes from their propensity for behavioral flexibility, but at the cost of prolonged immaturity and altricial needs. Primate infants are born seeking a familiar caregiver (most often a mother) that, evolutionarily, they expect will provide protection, nourishment, and warmth, as well as social stimulation and support in times of need (Bowlby 1982). Later, the infant must acquire the necessary social skills to become part of the larger society and the specific skills to adapt to their environmental setting. The necessary high levels of advanced cognition and cognitive complexity cannot occur without a prolonged period of learning and advanced brain potential. For primates, most brain cortical development occurs postnatally, and, while there is a clear genetic plan for brain development, synaptic and

axonal growth and pruning must have the right environmental input at the appropriate age, with normative neurodevelopment occurring only after certain expected experiences occur.

## Peer-Rearing

A major function of an attachment bond is to assure that proper input is provided to the infant so that normative development occurs. Evolution has favored mothers as the instrument to provide this input. Absent mother, age-appropriate neuronal development does not occur and developmental abnormalities persist, particularly in arousal regulation. To understand the influence of maternal presence and attachment, differential rearing-conditions are used among laboratory-living rhesus macaques. For these experiments, infant monkeys are assigned at birth to a mother-rearing, a peer-rearing, or a surrogate peer-rearing condition (see Shannon et al. 1998 for a detailed methodology). Briefly, mother-reared (MR) monkeys are raised by their biological mother in conditions approximating the natural environment. Peer-reared (PR) and surrogate-peer-reared (SPR) monkeys are separated from their biological mothers following birth and are hand-raised in a nursery for 30 days, at which time they have access to an inanimate, cloth-covered surrogate mother. At 30 days of age, PR monkeys are rehoused with 3–4 same-aged peers, to which they develop strong attachment bonds in nearly all cases. Starting at 30 days of age, SPR monkeys are giving access to 4 same-aged, similarly-reared peers for 2 h per day.

While PR monkeys receive social stimulation in the form of their peer-groups, their peers are not capable of regulating their arousal the way a mother can. SPR monkeys are also deprived of a mother's regulatory capacities, and are further deprived of normative social stimulation. Thus, via examining developmental differences between these three rearing groups, researchers attempt to disentangle the effects of maternal presence and peer presence on development in rhesus monkeys.

The absence of mother during periods of attachment formation results in SPR and PR

monkeys exhibiting infant-like clinging well into adolescence. SPR and PR monkeys appear to never learn how to be entirely independent and tend to attain lower social dominance rank positions than MR monkeys, with SPR monkeys occupying the lowest ranking positions (Bastian et al. 2002). Further, SPR and PR monkeys tend to engage in anxiety-driven, self-directed behavior (i.e., hair-pulling, self-biting, sucking on hands or feet) (Suomi 1991), whereas MR monkeys rarely engage in such behavior. PR monkeys tend to be more anxious overall, particularly in response to novelty (Higley et al. 1991b; Dettmer et al. 2012), suggesting that, with no mother to regulate their arousal, they remain chronically over-aroused. PR monkeys also tend to engage in anxiety-mediated high alcohol intake (Higley et al. 1991a), when compared to MR monkeys. Furthermore, PR monkeys tend exhibit infrequent, but more vigorous and wound-producing bouts of aggression than do MR monkeys, suggesting deficits in their abilities to self-regulate.

Brain differences are also present among PR monkeys, which exhibit enlargement in stress-sensitive areas of the brain (i.e., dorsomedial prefrontal cortex, dorsal anterior cingulate cortex) (Spinelli et al. 2010), when compared to MR monkeys. They also showed variety of central nervous system (CNS) deficits (Espinell and Higley 2013).

## Components of Attachment

For the majority of primates, the first weeks of life are spent in almost constant physical contact or at least in close proximity to their mothers, who provide for their physiological and psychological needs. Rhesus infants are unable to thermoregulate or find food adequately during the first 2 weeks of life, driving the fragile infant to cling to their mother for their every need. This is likely a crucial feature of forming an attachment bond, as the infant learns to trust their mother as the provider of their needs. Later, infants use their mother as a secure base from which they can safely explore, keeping within her in sight just in case their arousal becomes dysregulated. As a

student of the Yerkes-Dodson law, Harry Harlow noted how mother rhesus monkeys reduce their infant's arousal, becoming a source of security in a sometimes frightening, unknown world. Harlow had already challenged the prevailing learning theory of the day by showing that infant monkeys possess an inherent curiosity about the world, as they would repeatedly open a "peep-hole" to simply see what was outside when placed in an opaque box (1958). Harlow found that this drive to discover the world and to explore and play with peers is attenuated when an infant is over-aroused. The genius of his surrogate mother experiments was to show that a soft, terry-cloth surrogate mother possesses the primary features necessary for attachment to form, demonstrating the types of experiences that the brain requires for normative development. Real mothers allow infants to cuddle, leading to arousal reduction and reduced fear and anxiety. Subsequent studies showed the importance of warmth and vestibular stimulation, as lesser but additional aspects of arousal reduction and security of attachment (Harlow 1958, 1960).

When a mother is not available, infants will seek out an attachment figure that is most like a mother. In his seminal studies on mother-infant attachment in rhesus macaques, Harlow concluded that the attachment bond between an infant and a caregiver is not based purely on the physiological need for nourishment, a common viewpoint at the time (Harlow 1958). In this study, he separated infants from their mothers after birth and reared them in a nursery where they had access to a wire and a heated, cloth-covered, inanimate surrogate mother. To determine an infant's preference for the wire or the cloth-covered mother, Harlow put the bottle from which the infants fed on either the wire or the cloth-covered mother, forming two conditions under which he observed the duration of infant time spent on each mother. The availability of the food on the wire mother was clearly of negligible importance to the infants, which spent the majority of their time on the soft, warm, cloth-covered mother. The infants even went as far as to cling to the cloth mother, while leaning over to nurse off of the wire mother, maintaining

**Attachment, Fig. 2** Illustration of the infant motivation to form attachment bonds based on a specific set of needs that clearly go beyond the physiological need for nourishment early in life (Harlow 1960)

constant contact with the warm, cloth-covered mother (Fig. 2).

That the infants were observed seeking out comfort from a secure base, despite the availability of food elsewhere, suggests that it is a crucial component of the attachment bond. When an infant's arousal is dysregulated by fear or discomfort, they seek to be cuddled by a warm, soft mother on which they can count on to supply their needs.

Vestibular motion provided to the infant by the mother is also a component of the attachment bond for the first 6 months of life, as demonstrated by Harlow (1960). To investigate this, infant monkeys were given access to a constantly rocking, cloth-covered surrogate mother and to a stationary, cloth-covered surrogate mother at birth. For the first 6 months of life, the infants consistently spent more time on the rocking surrogate, suggesting that the kinesthetic motion that the mother provides is a part of the specific needs of the infant. After the infant is 6 months old, the duration of time spent on either of the surrogates is comparable, suggesting that, when the infant reaches 6 months of age, they are developed enough to provide themselves with adequate proprioceptive stimulation.

Contingent feedback, is another crucial component of the attachment bond. From this, the infant learns what is acceptable and what is not acceptable, and what they should fear and what they should accept as part of their world. Work by Mason and Kenny (1974) and Mason and Capitanio (1988) demonstrates that the availability of a secure base allows the infant to learn the basis of all future social skills, reciprocity, through contingent stimulation. They found that infants raised with dogs as surrogate-mothers (they both move and respond to the infant), were more likely to explore and showed more competent peer relationships. While dogs are not as adept as are mother rhesus monkeys to adjusting their behaviors according to their rhesus infant's needs, sensitive dog parenting was enough to meet the expected needs of the infant and adequate social skills developed. Furthermore, when Brunelli et al. (2014) gave infants access to responsive and non-responsive surrogate mothers, it was clear that the infants raised with the responsive surrogate mothers exhibited more confident behaviors, as well as improved social skills.

## Evolutionary Basis of Attachment

To Harlow, the central aspect of attachment was that a mother possessed both the qualities for survival and for normative psychological and socioemotional development. Studies suggest that sensitive parenting leads to reduced arousal (Levine et al. 1985) and, over repeated episodes, maternal reduction of anxiety and arousal induces survival and pruning of the cortical axons and synapses that project to and from the older mammalian stress and bonding centers of the brain, areas that attenuate the stress response (Zhang et al. 2005). The advanced cortical wiring of primates is based on the experience-expectant brain, with genetics providing a directional map and mothers providing the necessary input at the age-appropriate time.

John Bowlby, the founder of attachment theory, was an admirer of Charles Darwin's evolutionary theory and viewed attachment as a facet of evolution. In his book, *Attachment*, he describes

**Attachment, Table 1** Infant behaviors in separation paradigm are thought to be divided into phases, grounded in attachment theory, and based on the infant motivation to get back in close proximity with their caregiver

| Protest phase                                 |                                                                             | Despair phase                                                                                  |                                                                                                          | Detachment phase                            |                                                                                        |
|-----------------------------------------------|-----------------------------------------------------------------------------|------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------|---------------------------------------------|----------------------------------------------------------------------------------------|
| Behavior                                      | Evolutionary basis                                                          | Behavior                                                                                       | Evolutionary basis                                                                                       | Behavior                                    | Evolutionary basis                                                                     |
| Crying, screaming, increased motoric activity | Draw the attention of caregivers, to reduce the risk of injury or predation | Silencing, despondency, reduction of motoric activity, and fetal-positioning in rhesus monkeys | Reduce likelihood of injury from excessive movement and the likelihood of calling attention to predators | Resum normal activity without the caregiver | Cast off old attachment bonds in the preparation to make new bonds with new caregivers |

A

the influence of Harlow as central to the development of attachment theory (1969).

Trained as a psychologist and psychiatrist, Bowlby was struck by the response of human children to separation from their mothers for routine hospital procedures. Noticing the parallel responses of human and rhesus monkey infants to separation, Harlow’s studies of rhesus monkeys were critical in forming the theoretical model of attachment. While Bowlby noted that human infants display a specific sequence of behaviors when they are separated from their mothers, Harlow showed that rhesus infants vocalize loudly and ardently in attempts to elicit maternal retrieval. Infant motivation during separation from their attachment figure is largely based on getting back in close proximity with their caregiver, who offers them the best chance of survival (Bowlby 1969). If they are not retrieved by their caregiver, infants typically enter a despair phase, where their overall motor activity decreases and their cries cease. If the despair phase persists, some infants enter into a detachment phase, where they resume their normal activities, absent a caregiver. While these infants show maternal independence, they exhibit atypical responses to peers’ solicitations to play and to social challenge, suggesting that their development is impacted by the lack of a reliable, sensitive caregiver. When it is clear that the caregiver is no longer available, orphaned rhesus infants are sometimes adopted by other members in the troop, increasing their chance of survival to adulthood and allowing normative socioemotional development to occur.

Based on Harlow’s findings with rhesus monkeys, Bowlby believed that infant response

during separation is evolutionarily driven, and divided into phases, with responses in each phase optimally supporting the infant’s survival (see Table 1). These phases have been observed in most primate species undergoing an experimental separation paradigm, lending support to the evolutionary basis of attachment.

In the detachment phase, Bowlby saw the underlying change in behaviors shift from a focus on only mother to a post-mother attachment state. According to Bowlby, infants that find their caregiver no longer available prepare to form an attachment bond with a new caregiver. This was illustrated by Mason and Kenny (1974) while investigating attachment bonding between infant rhesus monkeys and dogs. Following separation from their familiar attachment-figure (the dog), infants entered into a protest phase and reacted in fear to unfamiliar dogs presented to them as potential new attachment-figures. This fear diminished rapidly and, thereafter, the infant monkeys spent their time in frequent contact with previously unfamiliar dogs, sleeping, playing, and remaining in close proximity, showing similar attachment-like behaviors as they did to their earlier surrogate-dog mother. When the previously unfamiliar dogs were separated from the infants for an exercise period, the infants now exhibited protest-phase-typical behaviors, suggesting that an attachment bond had been formed.

Attachment Quality

Bowlby’s student, Mary Ainsworth, was instrumental in developing methods of assessing the

quality of attachment (1979). While attachment quality has not been quantified in animals in the same manner that Ainsworth and her students did in humans, it is clear that the quality of attachment varies between mother-infant pairs. Even in rodent species, pups that receive normative maternal care (licking) show varying outcomes in response to how much they have been licked by their mother (Weaver et al. 2004). Parenting quality is a predictor of the quality of attachment-bond formation and is a feature of normative development. Monkeys reared in peer-groups without mothers show atypical development, likely because PR monkeys lack the maturity to modify their behavior sensitively according to their peers' needs. Thus, PR monkeys receive virtually no sensitive care, as their caregiver is absent and the feedback from their world is in the form of the fearful responses from their same-aged, equally maternally absent peers. Consequently, their development does not occur along a normal trajectory, and while Ainsworth's attachment styles have not been rigorously applied to other animals or primates, there is clear evidence that nonsecure attachments occur when an attachment source fails to respond sensitively to an infant's needs.

As further evidence, one study investigated attachment in PR monkeys through assessing specific attachment to most-preferred peers (i.e., "best buddies") versus familiar peers and unfamiliar peers (Higley et al. 1992). Subjects' attachment behaviors were compared to MR controls. In the home-cage, clear preferences for peers emerged. The behaviors that the subjects displayed with their most-preferred peer (i.e., ventral clinging, vocalizations, etc.) are comfort-seeking behaviors typically exhibited by infant monkeys toward their mothers to reduce arousal. To test for peer-preference, a focal animal was placed in a circular chamber with several clear plexiglass doors that could also be covered with opaque doors. Familiar animals from their PR group, including their most-preferred peer, as well as strange, same-aged animals were placed behind these doors. The doors were opened in a sequential manner, allowing access to their most-preferred peer, a familiar peer from their group, or

to an unfamiliar peer. Not surprisingly, subjects spent significantly longer time in close proximity with their most-preferred peer than with all the other animals combined, including with familiar peers from their natal group. They exhibited reductions in stereotypies (an indication of anxiety) when they were with their most-preferred peer, and decreased stereotypies when they were with any other animal. However, when compared to MR subjects, PR monkeys exhibited more vocalizations and more self-mouthing even in the presence of their "best buddy," which could be interpreted as a sign of a nonsecure attachment, as they failed to derive the same level of security from their "best buddy" as did the control MR subjects from their mothers.

Subtle differences in the mother-infant relationship can also lead to differences in attachment quality. For example, Rosenblum and colleagues (1984) have spent the past three decades studying mother-reared bonnet macaques (*Macaca radiata*). Experimenters varied the environmental demands for maternal foraging so that food was easily obtained (low foraging demand (LFD)), difficult to obtain (high foraging demand (HFD)), and in a third category of variable and unpredictable foraging requirements (variable foraging demand (VFD)). While on its face, it might seem reasonable to predict that the increased amount of time that HFD requires for the mother to obtain food would lead to maternal inaccessibility and a nonsecure attachment, the results showed that the unpredictable nature of VFD made maternal accessibility unpredictable and, consequently, led to what could be considered nonsecure infant attachment, with the infants showing less affiliation, more negative emotions, and a subordinate rank when compared to the infants from the other two conditions. Moreover the VFD group exhibited high CSF corticotropin-releasing-hormone (CRH), 5-hydroxyindoleacetic acid (5-HIAA), norepinephrine, and low growth hormone, suggesting deficits in CNS development. Many of these behaviors and the underlying CNS differences persisted into adulthood, suggesting long-term effects of early nonsecure attachment.

## Genetic Contributions to Attachment

Studies assessing genetic contributions to attachment in animals have focused on genes that have implications on stress-response and behavioral reactivity. For example, certain mu-opioid receptor polymorphisms (OPRM1) are thought to increase the activation of the endogenous opioid system (Barr et al. 2008), with infants carrying a G allele presumably experiencing enhanced feelings of reward when in contact with their mothers, as compared to infants not carrying a G allele. Indeed, Barr and colleagues (2008) show that infants with a G allele show significant increases in attachment-related behaviors at baseline and during periods of separation, when compared to infants not carrying a G allele.

Another gene commonly assessed in studies of attachment is the serotonin transporter gene (5HTT), with the short allele commonly linked to dysregulated serotonin system function and the long allele linked to normal functioning. It appears that early maternal deprivation modulates the effects of possessing a short allele, with PR monkeys with a short allele exhibiting deficits in central serotonin functioning, while MR monkeys with a short allele appear undifferentiated from MR monkeys with a long allele (Bennett et al. 2002). This suggests that early maternal presence may compensate for the effects of certain deleterious genes, while maternal absence may exacerbate the negative outcomes.

## Effects of Child Abuse on Attachment Outcomes

From the first day of life, mothers are a reliable secure base, providing protection and accessibility to resources (Kraemer 1997). With a secure base, novel experiences become learning experiences from which the infant learns critical information necessary to understand normative, social and nonsocial, cause-and-effect relationships. Infants generalize their experiences from the mother-infant relationship to their later

experiences, impacting how they relate to others in the future. If mothers cannot be relied on to provide a secure base, then, as infants become juveniles, they develop the same set of expectations about peer and other relationships (Ainsworth 1989).

Aberrant attachment relationships, relegate a primate to a life-long pattern of difficulty in social relationships, emotional deficits, and often a life of low social status and, at times, social ostracism. One of the most devastating effects on attachment is that of abuse by a mother. That an infant forms and maintains an attachment to its abusive caregiver speaks to the intense motivation for an infant to form an attachment. As the mother is the only secure base available to an abused infant, her abuse elicits increased infant attempts to cling and seek relief, which too often lead to more abuse. Periods of abuse are followed by periods of normative maternal care and solicitude (Maestripieri 1998). At an age that is critical to developing what Bowlby and Ainsworth would have characterized as “felt security,” abusive mothers reject, often aggressively, their infants’ attempts to cling to them and to use them as a secure base. This lack of sensitively responding to their infants’ psychological needs appears to have a more negative effect on infant developmental outcomes than the abuse itself, an indication of the importance of mothers adjusting their behaviors to sensitively respond to their infant’s needs. Consequently, a mother who abuses her infant creates a mother-infant attachment bond characterized by approach-avoidance. Her lack of sensitivity to her infant and coordination of her behaviors when the infant is aroused leads to an attachment quality that in many ways parallels the disorganized attachment classification seen in human infants that are abused and neglected, characterized by freezing, stereotypes, and other indices of stress and fear (McCarthy and Taylor 1999; Main and Solomon 1990; Lyons-Ruth et al. 2013).

There is an abundance of negative consequences for infants who develop in an abusive environment. For nearly two decades, researchers

at the Yerkes National Primate Center have studied a group of rhesus monkey adult females that abuse their infants. These abused infants show evidence of pathological negative emotionality: increased fear and anxiety to social stressors and high levels of aggression (Howell and Sanchez 2011). Studies suggest that abused infants develop a cognitive bias to classify facial cues as being aggressive (often even when the cues are not aggressive), and to respond to typical challenges with inappropriate levels of aggression (Howell and Sanchez 2011). Not surprisingly, they also show elevated levels of resting cortisol. Other measures of hypothalamic-pituitary-adrenal (HPA) axis functioning also show abnormal dysregulation. For example, in response to a CRH challenge, they show increased cortisol, but blunted adrenocorticotrophic hormone (ACTH), perhaps an indication of prolonged hypercortisolemia which leads to blunted ACTH (Sanchez et al. 2010). Interestingly, the effect on the HPA axis is more pronounced in abused female infants than in abused male infants. Abused infants also show high levels of epigenetic marks in genes that modulate white blood cell functioning, primarily due to early and frequent maternal rejections, possibly leading to a biological tendency for increased illness (Sanchez et al. 2007). Even as infants, abused subjects show evidence of biological damage, as evidenced by damaged, shortened telomeres. They show impaired central nervous system serotonin functioning, with low CSF 5-HIAA concentrations. They show reduced white matter in the cortex and as well as reduced white matter tract integrity (Howell et al. 2013). Risk for maternal abuse increases if the infant is born with the deleterious short allele of 5HTT (McCormack et al. 2009). Furthermore, there is evidence that females abused as infants are at risk to abuse their own infants when they become mothers. As shown by cross-fostering studies, female infants learn from their abusive mother to respond to their own future offspring as they were treated, with females who were abused infants much more likely to become abusive mothers as they reach adulthood and have their own offspring (Maestripieri 2005).

## Conclusion

The attachment bond between an infant and its caregiver is a critical feature of normative development for primates. Infants are born requiring that a specific set of needs are met by a caregiver, which must be reliable and sensitive to their changing needs, and which will provide them access to necessary resources to ensure their survival. As altricial infants do not have the capacity to self-regulate their arousal, their caregiver plays a crucial role in maintaining an optimal level of arousal in the infant through calibrating their parenting behaviors to meet the infant's needs.

Evolutionary theory suggests that attachment bonds have developed between mothers and infants to ensure infant survival to reproductive age and to ensure normative socioemotional development. Mothers or other caregivers tend to supply infants with experiences that promote this development. Individuals raised without their mothers tend to exhibit anxiety and reduced social skills, reducing their capacity to reproduce and become parents themselves. Individuals raised with abusive mothers tend to exhibit disorganized attachment bonds and neurodevelopmental deficits, and are at risk to abuse their own infants in the future.

Certain genetic and environmental factors are useful in understanding the development of the attachment bond. It is clear that both genetic and environmental factors play a role, interacting to produce the attachment bond. Understanding the impact of genetic risk and sensitive parenting on the attachment bond and the impact of attachment bond quality on later outcomes are central features of attachment research.

## Attention

David A. Washburn<sup>1,2</sup>, Jennifer M. Johnson<sup>2</sup>, J. Antonio Salamanca<sup>2</sup> and William Whitham<sup>2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

Attention, then, is the name given to a device, whatever its nature, whereby one stimulus has its effectiveness increased over that of others whose physical energy may be greater...a device to secure reaction to the most vitally important of several stimuli acting at once upon the organism. (Margaret Floy Washburn 1908, pp. 313 & 316)

## Definition

Attention – broadly defined as “selection for processing” – has been a focus of psychological inquiry since the birth of psychology as a science. Wilhelm Wundt, William James, James McKeen Cattell, Edward Titchener, James Mark Baldwin, Herman von Ebbinghaus, Walter Bowers Pillsbury, and other early psychologists studied and wrote about attention in the late 1800s and early 1900s. As is clear from the quote from Washburn’s (1908) classic *Animal Mind: A Textbook of Comparative Psychology*, researchers interested in *animal* thinking and behavior were also curious about the process by which organisms experience, to borrow the well-known phrase from James (1890), “...the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others and is a condition which has a real opposite in the confused, dazed, scatterbrained state which in French is called *distraction*, and *Zerstreuung* in German” (pp. 403–404).

Note that the focus of M. Washburn’s definition of attention emphasizes the selection and prioritization of stimulus information that does not compel observation and response by virtue

of intensity, priority, frequency, salience, or similar physical reason. Washburn described the process by which animals may arrest responses to prepotent sources of stimulation so as to select and to react to other channels of information. This, for Washburn and a host of scholars who followed her, became the signature of attention, demonstrated not so much in the fact that organisms respond to stimuli, but rather in the fact that they respond to a selected subset of stimuli – with selection not dictated solely by stimulus potency – accompanied by diminished response any unattended stimuli.

### Attention as Observing Responses

During the half-century period of American behaviorism, research on attention declined and changed dramatically. Indeed, there was considerable controversy during this period as to whether the construct of attention was even necessary and useful to account for nonhuman animal behavior (Roitblat 1987). Of the nearly 5000 publications indexed by PsycINFO prior to 2021 with “attention” as the subject term and “animals” as the population, only 1 (Dashiell 1920) was an empirical study published during the behavioristic heyday of 1920–1960, and attention was not the central focus of that maze-learning research. This, of course, reflects the more general trend in psychology during this period of history, as less than 1% of the PsycINFO publications in which “attention” is a subject term appear in the half-century following Watson’s (1913) behaviorist manifesto.

This is not to suggest that the experimental analysis of behavior ignored stimulus selectivity altogether; to the contrary, what had previously been inferred as “attention” was operationally defined as “observing responses” or some similar measurable behavioral indicators of selection. Studies of discrimination learning, especially those relating to the phenomenon of blocking, allowed researchers to investigate conditions in which animals that almost certainly sensed multiple simultaneous stimuli or stimulus features (e.g., the color and shape of a stimulus), only learned to respond to a subset of those cues (e.g., perhaps to

color). Other cues that were available in the stimulus array failed to control behavior discriminatively. In a classic blocking experiment, Kamin (1968) exposed rats to electric shock preceded by a signal. The signal was first comprised of a single element (e.g., noise). The signal was then compounded with a second element (e.g., light). Rat subjects responded to the first conditioned stimulus (i.e., noise) with a reduction in an appetitive response, but this behavior was not extended to a light signal when presented alone. Whether this pattern of behavior was due to the subjects not noticing the second stimulus dimension or intentionally ignoring it, the subjects demonstrated selection.

Like blocking, overshadowing is a phenomenon observed in traditional behaviorist experiments where animal subjects appeared to attend selectively. With overshadowing, subjects attend to one of two or more stimulus features more acutely due to salience. In the aforementioned blocking experiment, Kamin (1968) also presented rat subjects with compound stimuli in learning trials. That is, these rats were exposed to a simultaneous light and noise signal before the onset of electric shock. When the compound stimulus was decoupled, rats demonstrated more suppression of the appetitive response with the light signal than the noise signal. This again demonstrates that nonhuman animal subjects were able to sense both dimensions of the compound stimulus but were weighting these dimensions selectively. These results led researchers (e.g., Sutherland and Mackintosh 1971) to conclude that nonhuman animals employ two processes: one for the selection of relevant stimulus dimensions and a second for the relative weighting of these stimulus dimensions. Interpretations of these and similar blocking, overshadowing, and cue-competition studies produced learning models that included a limited capacity for the acquisition of unique associations (e.g., Rescorla and Wagner 1972).

The so-called cognitive revolution of the late 1950s and early 1960s was catalyzed in large measure by a return to the experimental study of attention by psychologists. Scholars like Donald Broadbent, Colin Cherry, Anne Treisman,

George Miller, J. A. and Diana Deutsch, Ulrich Neisser, and others brought information-processing (i.e., cognitive) perspectives to the study of limits and selectivity. The metaphors (e.g., filters and bottlenecks, resources, spotlights) and methods (e.g., vigilance, visual search, Stroop, flanker, cuing) from the study of human attention were applied by comparative psychologists to the study of animal cognition. Additionally, behavioral neuroscientists made substantial headway in the understanding of the neuroscience of attention through the use of animal models (e.g., see reviews by Posner and Petersen 1990; Pribram and McGuinness 1975). Whereas in recent decades, the cognitive neuroscience of attention has benefitted greatly from neuroimaging and electrophysiological studies of humans engaged in attention-related tasks (e.g., Hopfinger and Slotnick 2020; Rueda et al. 2015), this work has consistently been complemented (an indeed preceded) by studies of attention in animal models, using cell-recording, pharmacological interventions, and other techniques (e.g., Rahi and Kumar 2021). Animal research has informed much of what is known about the bilateral dorsal frontoparietal network that is active during controlled or endogenous attention, and the right-lateralized ventral frontoparietal stream that is implicated when attention is captured exogenously, as well as the brain structures within these pathways that are differentially activated by the different types or functions of attention. Thus, the dorsal and ventral pathways map on, appropriately enough, to “top-down” (i.e., concept-driven or goal-directed) and “bottom-up” (i.e., data-driven or reflexive) cognitive processing. The present review cannot do justice to the hundreds of published studies that examine the neurobiological mechanisms of attention in animals but acknowledges that this invasive work from behavioral neuroscience has frequently outpaced the purely cognitive and behavioral investigations of animals paying attention.

Similarly, any brief review of the behavioral research on animal attention is unavoidably selective. Attention has become a fruitful topic of investigation in comparative cognition;

additionally, many scholars who study other aspects of animal cognition have also contributed to the literature on attention. More detailed reviews of animal attention have been published (e.g., Bushnell 1998; Herbranson 2017; Roitblat 1987; Washburn and Tagliatela 2012; Zentall 2012). The goal of the present review is to highlight some of the major figures and most common behavioral paradigms that have contributed to our understanding of animal attention. As an additional caveat, it should also be noted that the present discussion ignores the substantial and growing comparative literature on social attention, including studies of joint attention, attention-seeking and -getting behaviors, and attention to social stimuli such as faces and dominance cues. These are interesting applications of attention for the study of social cognition but seem less relevant to the present more foundational review of what attention is and how it manifests in animals.

The comparative study of attention was greatly influenced by three of the first behavioral researchers to discuss the topic in the years following the cognitive revolution. Nicholas J. Mackintosh conducted early research and reviews that culminated in a theory of attention in discrimination learning (Mackintosh 1975). Donald S. Blough’s research program included innovative studies of visual search by pigeons – a topic also examined extensively by Patricia M. Blough (see review by Blough 2006). Donald “Al” Riley combined the aforementioned research topics, studying selective attention in pigeons’ discrimination-learning and visual-search performance, making both direct contributions to the understanding of processing of multidimensional stimuli (Riley and Roitblat 1978) and also inspiring other comparative psychologists to study attention and similar cognitive topics, many summarized in a published volume in his honor (Zentall 2013).

## Types of Attention

The work by these seminal scholars serves to illustrate two of the three primary types or

functions of attention that have been identified from extensive research with humans: Attention Focusing (i.e., selection, filtering, resistance to distraction, concentration) and Attention Scanning (i.e., shifting, switching, orienting, dividing). The third primary subskill of attention is Attention Sustaining (i.e., vigilance, alerting, watchkeeping, signal-detection; see Posner and Petersen 1990 for discussion of these three attention systems). This multidimensional character of attention has long been acknowledged, although there has been debate about the number and nature of the attention factors or types. Whereas there may be other identifiable attention skills, there is strong agreement about these three, and each has been examined in the animal-cognition literature. To date, sustained attention has been the least studied aspect with animals by far. Tests of sustained attention require animals to monitor a source of stimulus input (e.g., a computer display) or a period of seconds or minutes while they wait for the appearance of a to-be-detected stimulus. The signature finding associated with sustained-attention research is the vigilance decrement: responses are slower and errors (missed targets) are more frequent as the watch-period increases. Most of the literature on animal vigilance-related performance is neuroscientific in focus (see summary by Sarter et al. 2001), in which sustained attention is somewhat easier to test because the animals are commonly restrained so that the psychophysiological correlates of alertness and vigilance can be recorded. However, there are a few published behavioral studies of animals' capacity to sustain or extend attention (e.g., Bettie and Rosati 2021; Frigaszy et al. 2009; Maki 1975). Some of this behavioral work measures extended attention based on social cues, but more traditional testing paradigms have also been used, like signal detection paradigms in which an organism must respond to the presentation of a target stimulus, the appearance of which might be delayed for some period of time, and might follow presentation of a sequence of nontarget stimuli.

The scanning of attention is well illustrated by the visual search paradigm, a classic test of the spatial orientation of selective attention. The goal is to locate a target stimulus that is presented in a

simultaneous array of nontarget images, and to do so as quickly and as accurately as possible. Countless studies with human participants established the signature findings for attention in this paradigm: target-detection generally increases as the size of the search array increases, unless the target is physically dissimilar from the nontargets (e.g., finding a T embedded in an array of letters like C, G, and O), in which case, the target pops out with equal rapidity and accuracy irrespective of the number of nontargets. Set-size slopes correspond to the serial, spatial scanning of attention. Since Blough's systematic demonstrations of target location by pigeons, subsequent research on attention using the visual-search paradigm was conducted with primates, dogs, rats, birds, fish, and other animals (e.g., Cook et al. 2012; Tomonaga 2008; Washburn and Tagliatela 2006; Zhou and Desimone 2011). For example, Reichenthal and collaborators (2020) provided an extensive review of the visual-search literature in humans and animals, including new data showing serial-search and pop-out effects for archerfish performing a battery of visual-search tasks requiring location of target stimuli distinguished by color, size, shape, or a conjunction of features.

Attention shifting has also been studied using variations on a cuing paradigm. For tasks in which stimuli can appear in multiple locations, response time and accuracy may be facilitated by directing the organism's attention to the spatial location in which the target will appear, just prior to the presentation of that target. This shift in attention can be exogenous: for example, a flash to the periphery will elicit an involuntary shift toward the sudden flash or perceived movement. Conversely, organisms can be trained to divert their attention to a spatial location endogenously: for example, a symbolic cue (e.g., an arrow) might be used to train an animal to shift attention either to the left or the right of a fixation point. Faster and more accurate responses on cued trials than on uncued trials – or on invalid cuing trials, in which the target stimulus appears in a position other than the one that was cued – is taken as evidence of a covert shift in attention (Eckstein et al. 2013). Cuing tests such as these are popular for the study of human attention and have also

been employed in the study of attention with nonhuman animals. For example, Li and collaborators (Li et al. 2021) found that mice were significantly faster and more accurate in the validly cued compared to the invalidly cued trials, for both the endogenous and the exogenous conditions. In the most demanding form of the cuing paradigm – the antisaccade task – a cue in one stimulus location requires the shifting of attention in the opposite spatial direction. For example, a flash to the left of fixation signals that the discriminatory stimulus will subsequently appear to the right of fixation; thus, responding can be facilitated if the organism can resist the exogenous pull of the flashing cue and shift attention endogenously instead in the opposite spatial direction. This antisaccade task, which has proven to be one of the most important measures of the capacity to control the spatial orientation of attention in humans, has been successfully employed in the study of animal attention (e.g., Johnston et al. 2009). For example, Everling and DeSouza (2005) examined the role of the prefrontal cortex in resolving the competition between reflexive attention capture and goal-directed, endogenous shifts of attention by monkeys that were trained to make prosaccade (i.e., toward the flash) and antisaccade eye movements.

The antisaccade task makes a fitting transition to tests of attention focusing or concentration: endogenous or goal-directed control over the direction of attention shifting is also related to the intensive, mental-effort aspects of attention that are included in this dimension, frequently called “executive attention.” The focusing of attention has been studied with various procedures that indicate which stimuli have been selected for processing and response and which have been ignored (e.g., DeSouza and Everling 2004). To disambiguate the degree to which the organism is actually *selecting* (i.e., choosing which stimuli to process), in contrast to having attention elicited involuntarily on the basis of stimulus intensity or salience, it is typically necessary to put stimuli (or stimulus features) in competition with one another. That is, one studies attention focusing by testing organisms under conditions in which the to-be-responded-to

stimulus is not the most intense, salient, or prepotent cue. The aforementioned discrimination-learning paradigms provide one example of this strategy: Given stimuli with multiple features to which an organism may respond, some subset of the cues get selected and others – even others that would otherwise be most salient – get ignored (e.g., Castro et al. 2020; Leith and Maki 1975). Ironically, this means that the mark of focused attention lies in the fate of the unattended or unselected stimuli – or, as MF Washburn (1908) wrote, “The most fundamental characteristic of attention, then, is perhaps that aspect of it which has been called *abstraction*, the diminished effectiveness of stimuli not attended to” (p. 293).

Focused attention then is the promotion of some stimuli, particularly those that might not be selected for processing on their own strength, and the abstraction or demotion of other stimuli, despite what might be the natural predisposition to select these latter sources of stimulation. Nowhere is this activity of attention better (or, at least, more frequently) illustrated than in the Stroop paradigm (Washburn 2016). With thousands of articles on Stroop effects in the literature, the task is one of the most familiar in psychology. Participants are required to name the color of stimuli, which may themselves be incongruous or congruous names of colors (e.g., the word BLUE written in red, or the word RED written in red – where the correct response in both cases should be “Red”). Innumerable variations of the Stroop paradigm have been developed and tested, each pitting stimulus cues in competition with one another, and with the response requirements to ignore (if possible) the strong stimulus–response habits associated with one cue (e.g., the strong tendency to read and process word meanings) and to respond instead on the basis of the less potent stimulus–response association (e.g., name the print color). Relative to control conditions, such as naming the color stimuli like “XXXXX” or of noncolor words, responses are slower and more error-prone when the word–meaning and the word–color are incongruent. Conversely, responses may be facilitated when word meaning and word color are congruent. D. Washburn (2016) reviewed this literature and reported such Stroop-

like effects for rhesus monkeys tested on a numerical variant on the paradigm. On this variant, number-experienced monkeys were slower and less accurate to select the array of stimuli with more items when the stimuli in the arrays were themselves incongruent numerals (e.g., to select five 2 s as larger than four 7 s). On a range of variations on the task, other animals have also demonstrated the capacity to focus attention on relatively weak cues, albeit with interference from response competition from the stronger, prepotent stimulus dimensions.

Flanker tasks, in which a target stimulus is surrounded by congruent or incongruent flanking stimuli, have also been used extensively to study focused attention in humans. Ineffective concentration of attention is evidenced by interference or facilitation of the flanking stimuli, relative to trials in which target stimuli are unflanked or are surrounded by neutral stimuli. For example, Bramlett-Parker and Washburn (2016) reported that rhesus monkey could use top-down control to over-ride the bottom-up interference from incongruent flanker stimuli. You and Mysore (2020) similarly reported endogenous and exogenous attention by unrestrained mice in an innovative flanker paradigm.

Focused attention can also be demonstrated in relatively enhanced processing of the attended stimulus. For example, D. Washburn studied the effects of stimulus movement on learning, memory, and other cognitive processes. In a series of studies, humans and monkeys learned and remembered better when they had to use a joystick to pursue and catch moving stimuli on a computer screen, compared to when the stimuli remained stationary as the participants brought a computer-generated cursor into contact with each. This “stimulus movement effect” was not a result of attention capture from the natural predisposition to orient attention toward motion, but rather reflected the focusing of attention elicited by the mental effort required to capture the moving stimuli (Washburn 1993). In one study, the enhancement of learning and memory for stimuli that moved on the screen was accompanied by a decline in performance on a concurrent, secondary tone-detection task. This type of

complementariness in dual-task performance has been used in hundreds of studies with human participants to measure the allocation of attention resources between tasks, such that the more attention is concentrated on one task, the fewer processing resources are available for the concurrent secondary task. Smith and collaborators (Smith et al. 2013) provide an example of this dual-task paradigm in the comparative literature, reporting that monkeys showed disruption of attention-demanding uncertainty-monitoring performance (but not basic perceptual performance on a psychophysical judgment task) as their attention was demanded for a concurrent memory task.

## The Control of Attention

To summarize, psychologists have been curious about the selectivity of stimulus processing since its birth as a science, and have investigated with particular enthusiasm the following questions over the last 60 years: What is attention? How is attention realized neurobiologically? How is attention controlled or determined? Studies with animals by comparative psychologists and behavioral neuroscientists have helped to elucidate the multidimensional nature of attention and its neural substrates, complementing the findings from human cognition that attention serves functions that are captured by the popular attention metaphors of filters, spotlights, resources, gates, glue, and so forth. In reviewing these metaphors, Fernandez-Duque and Johnson (e.g., 2002) highlighted the debate over the answer to the third of the aforementioned questions – What are the determinants of attention? – by contrasting theories in which attention is the *cause* of selection, information processing, and behavior from those that describe attention as the *effect* of selection, processing, and behavior.

As noted above, the control of attention allocation between competing tasks or stimuli may sometimes be exogenous and reactive: selection is elicited involuntarily in response to environmental constraints like movement or novelty, or selection is conditioned reactively on the basis of experiential constraints like habits and priming.

At other times, attention is allocated endogenously, via the willful and effortful control of selection. In recent years, it has become common to refer to the willful, intentional allocation of attention as “executive attention” and there have been many studies in which animals’ capacity for this type of selection has been examined (e.g., French et al. 2018; Posner and Rothbart 2018; Rossi et al. 2009). The important conclusion is that, at every moment, there are at least these three sources of bias (environmental, experiential, and executive) vying for control over attention – and, by extension, control over behavior, because the effects of attending are measured behaviorally. The dichotomy between top-down and bottom-up control of attention is a second-order oversimplification (Awh et al. 2012) as it ignores the distinction between bottom-up reflexive attention-capture by change and motion and the bottom-up stimulus control that results from conditioning and experience, and that was the primary focus of attention studies with animals during the decades in which behaviorism held sway. Contemporary understanding of the control of attention reflects, perhaps, the clearest example of the cumulative achievements of our discipline, in which cognitive neuroscience builds on and complements the insights provided by years of systematic studies within the experimental analysis of behavior – principally animal behavior (Beran et al. 2016).

## Attention Bias

Marcello Siniscalchi

Department of Veterinary Medicine,  
University of Bari, Bari, Italy

### Definition

Attention bias is the tendency to drive or sustain attention to specific stimuli or types of information before others.

Attention bias is a phenomenon firstly noticed in humans during line dissection and cancellation tasks. In these neuropsychological tests, in which participants are required to search for and cross out targets, humans primarily attend to objects in the left side of space (Rogers et al. 2013). No longer viewed as a characteristic unique to humans, attention bias is widespread in the animal world, suggesting that this type of cognitive bias may be a fundamental feature of most vertebrate brains. Attention biases could manifest in any number of domains, but the most commonly studied varieties in the animal kingdom are visuospatial attention and social attention.

For example birds, like humans, primarily attend to visual items located in their left visual hemifield (Diekamp et al. 2005). The latter was

demonstrated during a food detection task (similar to the “cancellation” task used in humans) in which birds were required to sample food grains uniformly spread on a surface placed in front of them. A leftward visuospatial bias (right hemisphere activity) was observed in pecking activity over the experiment, supporting the specialization of the right hemisphere for visuospatial analysis (for review, see Rogers et al. 2013). This visuospatial attention bias may also be related to motor lateralization, as has been found in canine species (Siniscalchi et al. 2016). In this case, motor lateralization was first determined during a motor task in which dogs were selected for their preferential use of forepaws (paw preference) to hold a puzzle feeder device while eating its content (i.e., namely, the Kong test) (Siniscalchi et al. 2016).

Then, during a food detection task similar to that previously described in birds, a left-visuospatial bias in the total number of food items eaten from the testing apparatus (Fig. 1) was observed in dogs with a left forepaw preference during the Kong test, but a right-visuospatial bias was reported for dogs with a right-paw preference. No significant visuospatial attention bias was reported in ambi-pawed subjects (i.e., dogs that use both forepaws equally to hold the food device).

Biases during the allocation of social attention have been reported in nonhuman primates, birds, farm animals, and dogs. Like humans, macaques (*Macaca mulatta*) exhibit sustained attention toward potentially threatening social stimuli compared with neutral stimuli (pairs of adult male conspecific face images – one with an aggressive expression, one with a neutral expression) (Bethell et al. 2012). In a similar way, chimpanzees (*Pan troglodytes*) viewing a movie depicting naturalistic scenes involving the whole-body expressions of conspecifics looked longest at scenes depicting agonism, suggesting an attention bias toward threatening situations (Kano and Tomonaga 2010).

Eye gaze tracking methods have also been used to study attention bias during gazing behavior in different animal models. In dogs, results from eye

**Attention Bias,**

**Fig. 1** Experimental apparatus used to study visuospatial attention bias in dogs. The testing apparatus surface was divided into an array of seven identical vertical sectors to the right and to the left side of the central one “CTR.” For each dog, all food items within each sector were counted

tracking experiments show attention biases in their gaze behaviors which resemble those reported in primates studies: dogs exhibit prolonged attention on socially relevant visual stimuli like faces and eyes (eyes attention bias was irrespective of the emotional signals expressed by the face) (Somppi et al. 2016). In addition, the dogs preferred photos representing conspecifics over those depicting inanimate items or humans and exhibit specific attentional biases toward potentially threatening social stimuli (images depicting threatening dog faces) (Somppi et al. 2016).

Although emotion-related social attention biases have been repeatedly observed in animals (especially that of threat), the specific social features that are attended to preferentially are often species-specific. For example, humans look at the mouths of pleasant faces most, while dogs, chimpanzees, and rhesus monkeys show sustained attention toward threatening mouths compared to pleasant ones (Somppi et al. 2016). This difference may be due to the fact that the mouth area is a determinant cue in humans for the detection of a smile, but in both nonhuman primates and dogs it is relevant for the recognition of threatening social expressions (Somppi et al. 2016). The biological relevance of visual stimuli also plays a role in visual scanning strategies of threatening social signals since dogs look longer at threatening

conspecific faces than at other canine facial expressions, but avoided looking at heterospecific (human) threatening faces. This could be explained by the fact that conspecific faces are more biologically significant for dogs, eliciting a prevalent activation of the limbic pathways (e.g., the amygdala drives attention to arousing emotional stimuli) that led to sustained attention in the brain (Rogers et al. 2013; Somppi et al. 2016). Alternatively, avoidance behavior in dogs in response to threatening human faces could be driven by enhanced prefrontal modulation associated with submissive behavior or memory-based social evaluations (Somppi et al. 2016).

Attention biases towards threatening stimuli are enhanced when animals are in anxious states indicating a clear link between negative affective states and attention biases. For example, increased attention and vigilance toward a potential threat stimulus were observed in rhesus macaques in anxious states after a stressful procedure (Bethell et al. 2012). Similarly, in birds, increased threat perception (e.g., increased vigilance to an alarm call) was observed in starlings denied access to water bathing compared with birds that were able to water bathe, indicating that anxious birds (due to compromised flight ability) allocated more attention to the threatening stimulus (Brilot and Bateson 2012). Furthermore, pharmacological studies in farm animals demonstrated increased

attention towards the threat of a dog when both sheep and cattle were in a pharmacologically induced anxiety state compared with when they were in a calm state (Lee et al. 2017). Overall, these findings suggest that testing attention bias will open the door to new ways of measuring the affective states of animals with direct implications for animal welfare.

Behavioral studies indicate that attention bias to threatening stimuli is also affected by brain lateralization (i.e., the different specialization of the two side of the brain in both structures and functions) (for review, see Rogers et al. 2013). In dogs, a left gaze bias and an orienting head turning response to the left side were observed in response to human threatening faces (Racca et al. 2012) and alarming visual stimuli (Siniscalchi et al. 2010), respectively. Given that the lateral hemifield of each eye of most vertebrates projects mainly to the contralateral side of the brain, these results are consistent with a specialization of the right hemisphere for the analysis of threatening and arousal stimuli (Rogers et al. 2013).

Lateralization is a phenomenon distributed widely in the animal kingdom, and it manifests in many ways (from social attention to visuospatial attention); they are influenced by physiological state and brain organization and can have practical applications for animal handling and assessing their affective states.

### Synonyms

Attention-deficit disorder (ADD); Attention-deficit hyperactivity disorder

### Definition

It is a chronic mental health condition evident by persistent inattention, hyperactivity, and occasionally impulsivity.

### Introduction

Attention-deficit hyperactivity disorder (ADHD) is a neurodevelopmental disorder that can be diagnosed during childhood. Those who suffer from this mental disorder have trouble maintaining attention for a long period of time and exhibit uncontrollable impulsivity and restlessness. These patients find it difficult to coordinate and organize their thought processes. This hampers performance in academics, workplace, and social settings. Such performance deficits and the resulting behavior of others put individuals with ADHD at the risk of developing other mental disorders over time, such as oppositional defiant disorder (ODD), major depressive disorder (MDD), anxiety disorder, conduct disorder (CD), etc.

Although it is called a disorder of the childhood, diagnosis of ADHD in adults is also common (Daley 2006). It is likely that these adults must have had ADHD initially in their childhood, which was left untreated. Adults with ADHD are prone to substance abuse later in their life in order to cope with their disorganized life. This necessitates the early detection of ADHD in childhood as proper management and intervention plans can lead to a better prognosis.

In 1980, ADHD as a mental disorder first appeared in the *Diagnostic and Statistical Manual of Mental Disorders-III* (DSM-III 1980). It was known as attention-deficit disorder (ADD) as scientists categorized *inattention* as the highlighting feature of the disorder. While importance was also given to *hyperactivity*, it was mostly seen as a secondary complication. Thus, DSM-III stated it as ADD with or without hyperactivity. The following revised edition of DSM-III, known as DSM-III-R (1987), improved on the definition and treated *hyperactivity* and *impulsivity* as primary criteria along with *inattention*, thus changing its name to ADHD (Lange et al. 2010). DSM-IV (1994) further classified ADHD into three sub-types depending upon the group of symptoms that are dominant in the patient: inattentive type, hyperactive type, or a mix of both known as combined type. These sub-types are now referred to as clinical presentations in DSM-V (Association 2013).

The exact cause of ADHD is unknown, and consequently a treatment for this disorder is still a challenge for the scientific community. A myriad of novel treatment options have been sprouting each decade as the disorder is gaining more recognition. The disorder is deemed to be complex and heterogeneous in nature, and hence some physicians and researchers doubt over its existence, owing to the fact that almost every symptom can be found in other mental disorders and that it is idiopathic (Moncrieff and Timimi 2010). Currently, researchers are searching for better diagnostic markers based on objective neurobiological and genetic perspectives as detecting the disorder using the subjective criteria leads to potential misdiagnosis.

### Diagnosis and Symptoms

Detecting ADHD in early childhood is a challenging task for clinicians. Several symptoms such as difficulty in attention, impulsivity, anxiety, etc. are not unique to ADHD and share similarity with various other mental disorders. The absence of any defining etiological feature of ADHD makes differential diagnosis complex. Moreover, the inconsistencies between adult symptoms and childhood symptoms make the diagnosis even more intricate. DSM-V acknowledges the fact that ADHD symptoms are not rigid, and these clusters of symptoms can change as a person matures. A patient who displayed the inattentive subset of ADHD as a child could very well develop the hyperactive- or mixed-type subset of ADHD as an adult.

ADHD diagnosis takes place in several steps and varies from place to place as different clinicians follow different guidelines. In case of children, apart from direct observation, information about their behavior is usually collected from parents, colleagues, and teachers. It is believed that even in adults, the symptoms must have occurred somewhere in the patient’s childhood. Thus, accounts of their life history from various sources are immensely helpful to

the examiner. For diagnosis in children, the DSM-V criteria state that at least six symptoms listed in the guidelines (Table 1) should be present in either inattentive or hyperactive division and should persist for a minimum period of 6 months. In adults, at least five symptoms should be exhibited in either of the domains (Association 2013).

ADHD is often accompanied by emotional dysregulation. It is characterized by erratic behavior, aggression, frustration, and unstable emotion in patients. About 25–45% children and 30–70% adults with ADHD display this cluster of behaviors. Changes to motivation are also a highlighting feature, as it has been observed that patients with this disorder tend to prioritize immediate reward over delayed reward (Shaw et al. 2014). Thus, the presence of emotional dysregulation is helpful to diagnosis and increases the likelihood that this disorder might be present.

ADHD diagnosis is usually aided by rating scales to screen the symptoms and provide some objectivity to the listed criteria in the DSM-V. These scales constitute a set of questionnaires that assess the behavioral cues in order to measure the extent of impulsiveness and hyperactivity, which will determine the presence and severity

**Attention-Deficit Hyperactivity Disorder, Table 1** Criteria for diagnosing ADHD according to diagnostic and statistical manual of mental disorders V (DSM-V)

| Inattention                                                                                                                  | Hyperactivity and impulsivity                                |
|------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------|
| Unable to focus on details most of the times and carry out careless mistakes in schoolwork, work, or during other activities | Fidgets with or taps hands or feet or squirms in seat        |
| Has difficulty sustaining attention in tasks or play activities                                                              | Leaves seat in situations when remaining seated is expected  |
| Does not seem to listen when spoken to directly                                                                              | Runs about or climbs in situations where it is inappropriate |
| Does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace                   | Unable to play or engage in leisure activities quietly       |
| Organizing tasks and activities is difficult for him or her                                                                  | Is “on the go,” acting as if “driven by a motor              |
| Avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort                                    | Excessive talking                                            |
| Frequently loses things necessary for tasks or activities                                                                    | Blurts out an answer before a question has been completed    |
| Is easily distracted by extraneous stimuli                                                                                   | Find it difficult to waiting his or her turn                 |
| Is forgetful in daily activities                                                                                             | Likely to interrupts or intrudes on others                   |

of this disorder. Some common scales used are Conners rating scales; Swanson, Nolan, and Pelham-IV (SNAP-IV); Vanderbilt ADHD rating scales; ADHD Rating Scale-IV; etc. (Collett et al. 2003).

## Prevalence

ADHD is one of the most frequently diagnosed psychiatric disorders. Following the DSM criteria, its prevalence ranges between 3–10% in children and 4–5% in adults. This disorder occurs worldwide, and geographic location does not seem to influence its prevalence rate (Polanczyk et al. 2007). Although considered a disorder of the childhood, 50% of the patients carry this abnormality into their adulthood (Spencer et al. 2007). Sex differences are also visibly pronounced in ADHD as males are four to five times more likely to be diagnosed than females. This discrepancy can account for the genetic and hormonal differences between males and females, as well as the fact that males are more susceptible to environmental risk factors (Biederman et al. 2002; James 2008). Among those diagnosed, the male-to-female ratio for the combined type is about 3:1, while for the inattentive type, it is 2:1.

## Pathophysiology

Biomedical imaging techniques have revealed a notable disparity between the ADHD brain and normal brain. Structural MRI studies in children with ADHD have shown a reduced volume of the basal ganglia and prefrontal cortex (PFC), as well as reduced cortical thickness and abnormal white matter microstructure in various neural circuits associated with sustained attention, motor inhibition, and motivation (Batty et al. 2010; Nagel et al. 2011; Nakao et al. 2011). However, the reduction in volume and cortical thickness abnormalities were almost undetectable in adults. These observations are backed by a consistent set of longitudinal studies which suggest these changes attenuate as the person ages, insinuating a delayed

maturation of certain brain regions (Frodl and Skokauskas 2012; Shaw et al. 2007). Studies that focused on hippocampus and amygdala have also found volumetric differences. Emotional dysregulation is a common feature in ADHD patients and might implicate a link to changes in amygdala (Frodl et al. 2010). A deficit in the activity of prefrontal, premotor, and frontal-striatal circuits has also been reported in ADHD patients when monitored using PET and fMRI scans. Thus, even after all of these correlational findings, further elucidation needs to be carried out by researchers to establish these morphological differences as a causal factor for ADHD.

Neuropsychological functions such as cognition, attention, emotions, as well as memory and learning are regulated by intricate levels of neurotransmitters, noradrenalin, and dopamine, which work in conjunction. These functions are associated with a diverse range of interconnected neural circuits found in the brain regions such as PFC, caudate, and cerebellum. Several studies have reported reduced functionality of these neurotransmitters in the aforementioned brain regions and have been hypothesized to relate with the observed symptoms in ADHD. There are ADHD medications that antagonistically bind to dopamine and noradrenalin reuptake channels on the presynaptic neurons, which result in an increased levels of neurotransmitters at the synapse (Seiden et al. 1993). They also seem to inhibit monoamine oxidase, a family of enzymes that aids in the catabolism of these neurotransmitters (Pliszka 2005). All of these findings clearly indicate that stimulating the neurotransmission via direct agonists may mitigate the symptoms. However, drugs such as piribedil and amantadine do not seem to offer relief to ADHD patients, suggesting a much more complicated biology (Pliszka 2005).

## Genetic Studies

It has been long known that ADHD can be passed down through generations. Multiple studies conducted on family lineages and twins confirm its high genetic heritability ranging from 60%

to 90%, which is on par with that of bipolar disorder and schizophrenia (Hawi et al. 2015). It has become paramount for scientists to identify those genes to gain a novel insight into its functioning. Till date, no specific causal genes have been discovered, which hints at a multi-gene interaction that results in ADHD phenotype (Thapar et al. 2013). The observed changes to the neurochemistry of ADHD brain have provided incentives to look for gene variants associated with reduced dopaminergic neurotransmission (Spencer et al. 2005). Using the candidate gene approach, susceptible genes have been identified that encode for dopamine receptor sub-types D4 (DRD4) and D5 (DRD5), as well as dopamine transporter (DAT-1). Risk factors related to serotonin receptors have also been reported (HTR1B and SLC6A4) (Gizer et al. 2009).

## Treatment

Without a firm understanding of ADHD, formulating a concrete, evidence-based treatment plan is a challenging task for researchers. A complete cure for this disorder is yet to be discovered; however, some of the known treatment methods have displayed effectiveness in tackling the symptoms so that they do not interfere with their daily life.

## Pharmacological Interventions

Pharmacological intervention techniques have paved their way into clinical practice since the understanding of the neurochemical basis of ADHD. They have proved efficacious in bringing about symptomatic relief and are recommended by various physicians to ADHD patients with mild to severe impairment (Kendall et al. 2008). The first-line of medication includes the prescription of stimulants, a class of psychoactive drugs that elevate the brain activity. These drugs increase the overall availability of the neurotransmitter dopamine and noradrenaline at the synaptic sites (Pliszka 2007). The most widely used among them are amphetamines and

methylphenidate and have been approved in the USA by the Food and Drug Administration (FDA).

However, the benefits provided by these psychostimulants are not without risks. Physicians therefore strictly adhere to the clinical guidelines and follow dosage limit set by the international standards. These drugs are known to cause mild alterations to cardiovascular physiology, such as an increase in the blood pressure and heart rate, and hence may pose threat to patients with risk of cardiovascular diseases. For that reason, medical examination of the patient is carried out before any pharmacological therapy can be recommended. Psychostimulants are highly susceptible for substance abuse. These drugs modulate the dopamine levels in certain brain regions involved with reward and euphoria, which increase the chances of developing an addiction (Lakhan and Kirchgessner 2012).

Physicians may resort to non-stimulant medication as a second line of treatment if stimulants fail to provide symptomatic relief to ADHD patients. A well-known non-stimulant for ADHD is atomoxetine, a non-epinephrine reuptake inhibitor. This drug is also known to inhibit the dopamine reuptake in certain brain regions such as the PFC (Sauer et al. 2005). It also has a lower risk for abuse as it does not act on the striatum, unlike the psychostimulants, and hence is preferred for patients with a history of substance abuse (Banaschewski et al. 2004). Atomoxetine is less efficacious than methylphenidate thus chiefly serves to function as an alternative medication (Hanwella et al. 2011).

## Non-pharmacological Interventions

Behavioral therapies are usually the first line of treatment recommended for children with ADHD (Kratochvil et al. 2009). Most of these include parental interventions, cognitive behavioral therapy, social skill improvement programs, psychoeducational programs, etc. (Association 2013). These management programs strategize by coordinating with child's parents designing sessions that involve various

physical and psychological activities ranging from puzzle solving to aerobic exercises. Early interventions in academic environment can also bring visible relief and a better prognosis for the child. Coordination by the teacher and colleagues can result in better school performance (Tresco et al. 2010).

## Conclusion

ADHD is a common neurobehavioral disorder that begins in childhood and often continues to adulthood. Estimates show two out of every three children with ADHD continue to have symptoms later on. There are three basic types of ADHD: primarily inattentive type, primarily hyperactive/impulsive type, and the combined type. All types are identified by the symptoms of hyperactivity, impulsivity, and inattention. Children with ADHD have difficulty in making and keeping friends, and if left untreated, it may interfere with daily life activities at school and work. It also hampers the social and emotional development.

## Introduction

Attention-getting behaviors (AGB) are described as communicative cues that aim to gain attentional state of the audience. They will mostly cluster into

visual, auditory, or tactile signals, depending on the perceptual system used. Intentional nature of communicative cues has been highlighted as a crucial feature in animal communication systems (e.g., for a review: Townsend et al. 2017). For instance, several species (e.g., in great apes: Halina et al. 2013; Prieur et al. 2016a) have been shown to communicate with each other by gesturing. To be considered as intentional, gestures must fulfill several criteria (Bates et al. 1975; Leavens et al. 2005): (1) the gesture is goal-oriented and the signal persists or is completed with other signals until the desired outcome is reached; (2) the gesture is adjusted in accordance to the attentional state of the audience, whose attention can be regained by the use of additional attention-getting behaviors; and (3) the gesture is supported by visual orienting behaviors alternating between the recipient and the distal object of interest (gaze alternation). While gestural studies highlight potential intentional communication, similar evidence from animal vocal communication is still debated. But some studies suggest that vocal and nonvocal sounds are used intentionally. For instance, Campbell's monkeys (*Cercopithecus campbelli*) use vocalizations in a controlled manner that implies flexibility and intentionality (Lemasson et al. 2013). Moreover, multiple studies have shown vocalizations to be dependent on the surrounding social audience in a variety of species (e.g., Marler et al. 1986), suggesting that these sounds are used intentionally.

Here, we will focus on various aspects of attention-getting behaviors that are used intentionally in humans and animals. AGB are used to communicate with conspecifics in social contexts such as play, grooming, moving, or agonistic encounters (Prieur et al. 2016a). Also, these behaviors can be exhibited by domestic and/or captive species interacting with humans (interspecific context), to request distant objects or food. (e.g., Maille et al. 2012). This happens particularly when the recipient is not responding or is not attending. Thus, AGB can be observed during spontaneous social interactions or, experimentally, by observing subject reaction according to the visual attention of the experimenter with special emphasis on the state of the eyes (open

vs. closed) and how flexibly the subject tailor visual- and auditory-based behaviors to elaborate their communication as a function of whether or not the experimenter can see them (Bourjade et al. 2014; Gaunet 2010; Malavasi and Huber 2016).

AGB are characterized by using visual modality stimuli such as alternate gazing or deictic gestures (i.e., mechanically ineffective body movements made to elicit specific behaviors on a recipient, repeated until the effect is obtained or failure is clearly indicated, Bates et al. 1975), such as begging gestures, defined as gestures produced toward an item placed just in front of a recipient or held directly in the recipient's hand(s), whereas pointing gestures are produced toward an external item of the environment (e.g., Maille et al. 2012). AGB could also be characterized by auditory-based gestures such as banging (e.g., Bourjade et al. 2014) or slap hand and clap hand (Prieur et al. 2016a) or vocalizations (Hopkins et al. 2007). This entry will explore attention-getting behaviors in different modalities and their development, mechanisms, and functions in human and animal species.

## Development

The attention-grabbing quality of the human infant cry is well recognized (Dudek et al. 2016) as well as those from distress calls in different species (Newman 2007). In human, from 3 months of age, and throughout the first year, vocalization rate increases (Camp et al. 1987). It has been noted that the child's limited vocabulary between 1 and 1.3 years old seems to serve only for denoting attention to an object or an event, with true lexical functions coming in between the ages of 1.3 and 1.6 years old (Camp et al. 1987). Prelexical comment demonstrated an early capacity for conveying topic and comment together in the form of speech sounds combined with an attention-getting gesture well before the emergence of multiple-word utterances.

Infants produce some hand forms resembling pointing gestures very early in their development. Index-finger extensions are visible in infants as young as 3 months (for a review: Rohlfing et al. 2017). Some authors (e.g., Bates et al. 1975)

presume that these gesture-like hand forms serve infants' own attention regulation and are coupled with object exploration. In human infants, the most frequently used communicative type is deictic hand gesture, and these emerge between 9 and 12 months (Rohlfing et al. 2017). Within their second year of life, infants point increasingly using their index finger rather than their whole hand; this form seems to be related to other advances in communication such as pointing comprehension or later language. In addition, around 18 months of age, some authors observed that infants begin to coordinate their gesture and gaze systematically and to ascertain that the partner is looking at them before pointing (Franco and Gagliano 2001). Finally, there is a developmentally prior coupling between the vocal and motor systems. Iverson and Fagan (2004) studied arm gestures in infants as young as 6–9 months and found a temporal coordination of canonical babbling with rhythmic hand movements, an important basis for the integrated speech-gesture system.

For nonhuman species, visual signals (e.g., body postures, movements, and facial displays) have been reported at early stage of life. Facial expression has been reported in rhesus macaques (*Macaca mulatta*) on the first day of life (e.g., Ferrari et al. 2012). In other macaque species (e.g., *Macaca tonkeana*, *Macaca silenus*), playful facial expressions are typically performed by infants to initiate social play. During ontogeny, the play face (PF; mouth opened with only the lower teeth exposed) is replaced by the full play face (FPF; the mouth is opened in a relaxed mood with both upper and lower teeth exposed (Palagi 2008)). However, nonhuman primate (NHP) infants appear to display few visual and tactile signals compared with the richness of their vocal repertoire (Maestripietri and Call 1996).

Communicative gesture could present different patterns. For instance, captive bonobos infant (from 10 to 24 months) expresses different action to initiate mother carries, such as grab side/venter, spread legs, step foot, and spin body (Halina et al. 2013).

## Mechanisms

For communication in humans, most of the language functions are under the control of the left

hemisphere of the brain and involve neural networks in which Broca's and Wernicke's areas play a key role for the production and for the comprehension of language, respectively (Meguerditchian et al. 2011). The study of manual asymmetries for gestural communication in apes and monkeys constituted an indirect approach to investigate the brain and neural basis of communicative attention-getting gestures. For instance, studies at the population level in chimpanzees and gorillas showed predominantly performance of attention-getting behaviors (e.g., slap hand and clap hand) with the right hand (Prieur et al. 2016a, b). Signalers used their hand ipsilateral to recipients for tactile and visual gestures and their contralateral hand for gestures involving auditory communication and a communication tool. These recent results further support the hypothesis that laterality in gestural communication might represent a precursor of the left-hemispheric lateralization of language. Producing attention-getting behaviors also requires cells functioning for recognizing a conspecific (e.g., in the anterior superior temporal sulcus). Authors as well reported the activity of a cell responsive to attention down (i.e., head, eyes, and body posture directed down) (for a review, see Emery 2000).

Some studies proposed that particular mechanisms are involved in the production ability of AGB such as individual learning through a process slightly different than ontogenetic ritualization (i.e., the forms that behavior takes derive directly from the social interactions in which an individual participates; Tomasello 2008). In this process, a signaler learns that when he performs a certain action (such as one that produces noise), this has the effect of drawing the attention of a nearby agent. This then leads the signaler to later produce that action intentionally with the purpose of drawing attention. Such learned attention getters in apes might include gestures such as clap, slap object, and tap other (Halina et al. 2013). Other studies support the hypothesis that social learning participates in the acquisition and use of attention-getting vocalizations as well as gestural communication such as auditory gestures (e.g., in chimpanzees: Prieur et al. 2016a; Tagliatalata et al. 2011).

Attention-getting behaviors are also reflecting underlying processes such as mutual attention

(gaze of individuals A and B is directed to one another) and joint attention (individual coordination with others' attention to external targets) (Emery 2000). Joint attention could correspond to the use of a social agent to obtain an object or the use of an object to obtain attention from the social agent; thus, in both cases, attention-getting behavior could be involved until achieving a certain goal and could be seen to be examples of cognitive ability for means-ends reasoning (Leavens et al. 2005).

### Functions and Behavioral Differences According to the Studied Species

The first function of attention-getting behaviors is to communicate with another social agent. In the case of interspecific context, most of the studies on human-animal interaction report attention-getting behaviors expression to obtain food. This happens particularly when the recipient is not responding or is not attending. Thus, AGB can be characterized by observing subject reaction according to the visual attention of the experimenter. For instance, olive baboons (*Papio anubis*) will express auditory-based gestures consisting of banging a plexiglas panel when experimenter is not visually attentive or visual orienting behavior that took the form of gaze alternation bouts between the experimenter's face and the food (Bourjade et al. 2014). It has been shown that red-capped mangabeys (*Cercocebus torquatus*) showed more and faster begging gestures (for food) when both the body and the head of the experimenter were oriented toward them than when they were oriented away (Fig. 1) (Maille et al. 2012).

Bottlenose dolphins (*Tursiops truncatus*) convey the attention of a recipient to a food target by maintaining the alignment of their bodies with it while alternating gaze between the target and the recipient (Xitco et al. 2004).

In domestic species, attention-getting behavior could also reflect communication with a human observer about the location of an unreachable reward. Experiments showed that domestic dogs (*Canis familiaris*) use alternate gazing when communicating the location of a hidden target (toy or food) and even adjust their own position in space

**Attention-Getting Behaviors, Fig. 1** Left-arm begging gesture performed by a juvenile male red-capped mangabey, (Maille et al. 2012)

to gaze at their owner according to the direction of the owner's gaze (e.g., Gaunet and Deputte 2011). When dogs obtained a different target to the requested one, they showed persistence in attention-getting behaviors, i.e., repeated gazes and vocalizations until they obtained the correct target, but did not elaborate their requests; e.g., no new behavioral technique emerged (Gaunet 2010). Domestic horses (*Equus caballus*) communication with a human experimenter about the location of a desired target was explored with a bucket of food out of reach. The rate of gaze alternation and indicative (pointing) (Fig. 2) and non-indicative (nods and shakes) head gestures was higher when the experimenter was frontally oriented toward the horse. Horses also elaborated their communication by switching from a visual to a tactile signal (i.e., prompting action via physical contact) when the experimenter was not attentive and demonstrated perseverance in their communication (Malavasi and Huber 2016).

AGB could also reflect an attachment signal toward human. Ohkita et al. (2016) focused on domestic dogs' attention-getting behavior such as whining and whimpering, looking at the owners' faces, pawing, and approaching in response to their owners' direct gazes. When the owners gazed at them, the durations of whining and whimpering and looking at the owners' faces were longer than when the owners averted their gazes. Attention-getting vocalizations toward

**Attention-Getting Behaviors, Fig. 2** Pictures of (a) gaze to the experimenter and (b) point at the bucket in horses, (Malavasi & Huber 2016)

humans have also been described in captive chimpanzees to request food. Three attention-getting vocalizations have been identified including the “raspberry,” the “extended grunt,” and the “kiss” (Hopkins et al. 2007). It has been shown that these attention-getting vocalizations are socially learned and voluntarily and selectively produced to capture the attention of an otherwise inattentive human (Hopkins et al. 2007).

In more spontaneous context, some studies showed the expression of ground hand slapping when a young gorilla wants to “invite” a social partner to play (Pika et al. 2003). Moreover, in play invitations, young apes produce significantly more visual signals when the social partner is attentive but more auditory or tactical gestures when the recipient is inattentive (e.g., (Pika et al. 2003).

## Conclusion

Attention-getting behaviors are communicative cues that aim to gain attentional state of the audience. They are mostly cluster into visual, auditory (vocal and nonvocal), or tactile signals. They happen particularly when the recipient is not responding or is not attending. Thus, in order to characterize AGB, methods can use observation of spontaneous social interactions or experimentation, by observing subject behaviors according to the visual attention of the conspecifics or an experimenter. If the subject is able to use this behavior in a flexible way, it suggests that he

comprehends its meaning. The signaler has previously learned that when he performs a certain action (such as one that produces noise), this has the effect of drawing the attention of a nearby agent. This then leads the signaler to later produce that action intentionally with the purpose of drawing attention.

It is nevertheless important to take into account that some behaviors that are used as attention getters can change their function with conditions. For instance, subject rate of gazes toward the request distant objects or food can be interpreted as a “waiting” reaction, whereas gazes used during alternation (with the experimenter) will give a communicative meaning (Gaunet and Deputte 2011; Malavasi and Huber 2016).

Finally, different patterns of attention-getting behavior exist, some are species specific, but more comparative research in other species is hence needed and further questioning between patterns per se in order to understand whether expressing alternative gazes, pointing (i.e., toward an external target), begging (i.e., from an experimenter), nonvocal auditory sounds, vocalization, or tactile stimulation requires differential cognitive means for attracting the partner’s attention.

and Physiology, University of Wyoming,  
Laramie, WY, USA

Animals use a variety of complex signaling mechanisms to convey information to conspecifics and heterospecifics alike. Among those modalities, acoustic signaling is a widespread behavior across vertebrate groups. Acoustic signals can carry information over long distances, and precise changes in frequency and temporal sequencing can encode high-resolution information in a very efficient way. These signals generally contain information about traits of the individual producing them, and they can divulge everything from the individual's location in space, to its identity, physiological state, and even complex semantic content as in the case of human speech. Together, these features make acoustic signals and the associated auditory processing and perception an excellent means of communication.

---

## Behavioral Value of Hearing and Acoustic Signaling

Acoustic signals move at great speeds through the environment and can be detected at long distances from their source. Therefore, auditory perception affords an excellent means of detecting and localizing other individuals in the environment. That ability can confer an advantage in noticing the movements of possible prey or detecting the approach of a nearby predator. Even beyond those unintended signals associated with movement, acoustic signals can also be produced intentionally

in the form of vocalizations such as alarm calls. Because sound radiates from its source in all directions, these calls can inform the behavioral responses of many individuals, including members of the individual's own species and eavesdropping members of other species. For example, Madagascar spiny-tailed iguanas (*Opluris cuvieri cuvieri*) eavesdrop on the alarm calls that Madagascar paradise flycatchers (*Terpsiphone mutata*) produce in response to detecting a nearby predator (Ito and Mori 2010). Those two species share a mutual threat, and iguanas become hyper-vigilant in response to flycatcher calls (Ito and Mori 2010). Thus, by eavesdropping on the acoustic signals produced by species that are similarly wary of specific nearby predators, it is thought that this helps iguanas evade predation.

Another key aspect of acoustic signaling and auditory processing is the recognition of individual identity. Identifying individuals is critical for distinguishing a mate, kin, or a threat from others within a group, and recognition of individual participants is necessary for almost all social behaviors. For example, wolves (*Canis lupus*) are capable of recognizing individuals based on the acoustic characteristics of their howls (Palacios et al. 2015). Similarly, female northern fur seals (*Callorhinus ursinus*) learn the calls produced by their pups, and a female will approach speakers that play the calls of their pups but ignore speakers playing the calls of other pups (Insley 2000). The elements of the nervous system that underlie that form of auditory processing incorporate not only sensory areas but also areas involved in memory, as a female seal's ability to use auditory processing to recognize her offspring persists even after several years of separation (Insley 2000).

Along with revealing an individual's identity, acoustic signals may also serve as an indicator of the individual's physiological state. For example, the vocalizations of rock hyraxes (*Procavia capensis*) contain cues about the physiological state and social rank of the individual (Koren and Geffen 2009). These examples are just a few of the almost innumerable cases in which acoustic signals and auditory perception play fundamental roles in the lives of many different types of organisms.

## Hearing in Birds and Mammals: Structures and Mechanics

Upon first inspection, a striking difference between mammals and birds is the presence of pinna in mammals, such as the prominent ears on rabbits and many dogs, but the absence of any such structure in birds. Those external structures in mammals are thought to confer an advantage because they help to funnel sound into the ear canal, making even very faint sources of sound easier to detect (Yost 2006). Beyond that external difference, however, the physical structures involved in detecting and processing sound are broadly similar between mammals and birds. For example, both groups have ear canals that are open to the surrounding air and that are diametrically opposed on the sides of their heads. This arrangement enables organisms to compare the timing with which a signal hits one ear first and then the other ear some brief time later. This interaural comparison is an integral component of how animals localize the source of that sound, reminiscent of how widely spaced eyes facilitate perception of visual depth. Despite the absence of pinna, some birds use the shape of their heads and specialized feathers to help funnel sounds into the ear canal in a way that is especially beneficial in detecting the location of the sound source (Wagner et al. 2013). Thus, similarities emerge even in the case of the most obvious anatomical difference between mammals and birds if we investigate the system more carefully.

When sounds are produced in the environment and detected by the auditory system, acoustic energy propagating as vibrations of molecules in the air enters the outer ear and causes movement of the structures that transduce that energy into perception of sound (Yost 2006). Through the action of pinna or specialized feathers, acoustic energy is funneled into the canal of the outer ear, where it is eventually captured and transduced into neural activity by the remaining structures of the middle and inner ear.

In the middle ear, membranes and small bones serve as a conduit for the transmission of sound from movement of air into movement of the fluid in the inner ear (Yost 2006). Through those

intricate mechanisms, the movement of air molecules that is inherent to acoustic energy is converted into motion of fluid in downstream structures where those motions are eventually transduced into activity of auditory neurons (Yost 2006). This transduction of acoustic energy and the associated physical motion into activity of neurons in the inner ear is broadly conserved across vertebrate groups (Manley 2017), but the structures and mechanisms that are employed to achieve sound transduction vary.

In both mammals and birds, acoustic energy in the canal of the outer ear impacts a thin membrane called the tympanic membrane (commonly called the “ear-drum”), and the tympanic membrane induces motion of a set of tiny bones that are collectively called the ossicles (Tucker 2017). These small ossicles within the middle ear are connected to form a chain for transmission of movement from the tympanic membrane to the opening to the inner ear known as the oval window (Yost 2006). At this level of resolution, additional differences begin to emerge between this system in mammals and the set of corresponding structures in birds, particularly in the number and relative orientation of the ossicles. For example, the ossicles consist of three bones – the malleus (hammer), incus (anvil), and stapes (stirrup) – in mammals and one bone – the columella – in birds (Tucker 2017; Yost 2006). Despite those structural differences, each of those systems achieves the same function of transferring movement and pressure from the outer ear, through the middle ear, and into the cochlea in the inner ear. For both groups, that pressure results in movement of the fluid and membranes within the inner ear. One of those membranes, the basilar membrane of the cochlea, contains sensory hair cells that are very sensitive to movement of the surrounding fluid. When those movements occur, they induce changes in the voltage of the hair cells, and those changes in voltage can be detected as electrical impulses, called action potentials, in neurons in the auditory nerve (Yost 2006). In both birds and mammals, these hair cells are the first step in routing auditory information into the central nervous system.

This comparison between mammals and birds makes it clear that nature has solved the challenge

of auditory processing in several different ways. Behavioral studies performed using those groups and others have revealed that auditory information serves similar purposes across many species (e.g., localizing sound sources, permitting communication and social interactions). Many of the studies that have revealed what we know about these processes have been performed in birds, and for that reason many of the examples described in the remainder of this text focus on lessons learned from studies of birds.

## Auditory Processing of Sound Location

The ability to resolve the location of a sound source is quite beneficial for detecting features of the ambient environment. This process is driven by comparing the timing of sounds arriving at each ear, with the sound produced by a specific source arriving first at the ear that is closer to the source and later at the ear that is farther from the source (Fig. 1). Mammals and birds have auditory systems that are excellent at localizing sounds by computing with millisecond accuracy the differences in time that it takes sound to reach each ear (Ashida and Carr 2011). The seminal studies that revealed this neural mapping of auditory space were performed using barn owls (*Tyto furcata pratimcola*) (Knudsen and Konishi 1978). Those owls are nocturnal predators, and they are exceptionally good at locating prey using only acoustic signals even in complete darkness. In order to locate their prey, such as a scurrying mouse, they rely on hearing and specifically on a mechanism called “coincidence detection” (Fig. 1). In this mechanism, action potentials associated with sounds arriving at the left and right ears are relayed to a specialized set of neurons in the brainstem (Wagner et al. 2013). Each of these specialized neurons receives input from each ear. Activity from either ear alone is not sufficient to activate those specialized brainstem neurons, but activity from each ear simultaneously is sufficient to activate those cells (Wagner et al. 2013). This requirement of activity from multiple inputs at the same time is the origin of the name “coincidence detectors.”

**Auditory Processing and Perception, Fig. 1** The location of a sound source in the surrounding environment gives rise to activity at a specific location within a specialized neural network. **(a)** Acoustic energy generated by the mouse's movements or vocalizations reaches the owl's left (L) and right (R) ears at different times and with different intensities depending on the mouse's location in space. In this case, the left ear receives an earlier and more intense stimulus compared to the later and less intense signal received by the right ear. The difference in time of arrival between each ear is the interaural timing difference.

(Adapted from Fig. 1 in Knudsen 2002). **(b)** Coincidence detector neurons in the auditory brainstem (nucleus laminaris) receive input from each ear with different latency. Input from either ear alone is insufficient to activate those cells (filled circles), but those neurons respond robustly (open circles) when input from both ears arrives at the same time. Thus, each coincidence detector neuron becomes an indicator of the position of a sound source in the surrounding environment. (Adapted from Fig. 1 in Salomon et al. 2012)

Through an elegant means of comparing the latency of activity from the left ear versus the latency of activity from the right ear (Fig. 1), each neuron in the brainstem population becomes an indicator of a discrete interaural time difference. Activity from each ear propagates centrally from the ear to these brainstem neurons, and in nearly all cases, the activity from one ear affects a given brainstem neuron at a different time than

activity from the other ear. But at one point in that convergence from each ear onto these brainstem neurons, activity from each ear reaches a given cell at the same time (open circles in Fig. 1b). In that case, coincident input has occurred and that cell is activated (Fig. 1). Neurons that perform this comparison of arrival times in each ear reside in the nucleus laminaris (NL) in the brainstem of birds and in the homologous medial superior

olive (MSO) in the brainstem of mammals (Ashida and Carr 2011). Thus, the activity of a given coincidence detector neuron indicates the presence of a sound source at the corresponding point in the surrounding space, enabling the organism to identify the position of the sound source in the horizontal plane. Barn owls have the additional impressive trait of asymmetric ear openings, with one ear biased toward detecting sounds that come from sources below the owl's head and the other ear biased toward detecting sounds from sources above the bird's head (Wagner et al. 2013). In this way, barn owls are able to detect the position of a sound source along both the horizontal and vertical axes, revealing the position of that source in high resolution and all as a result of auditory input even in the absence of visual input.

### **Auditory Processing of Social Information**

In addition to serving as a beacon of the location of a sound source, many acoustic signals such as speech and songs performed by birds also convey important social information. For example, song plays many key roles in songbird social behavior, including revealing the singer's identity, helping the singer establish and maintain a territory, and playing a central role in courtship and mate choice (Catchpole and Slater 2008). In most of the species that have been studied, especially those that reside in North America, male birds sing but females do not (Catchpole and Slater 2008). That ability of male birds to sing is associated with a network of specialized brain sites that are large and obvious in the male brain but are atrophied to much smaller sizes or are absent in the female brain (Mooney et al. 2008). Intriguingly, male songbirds learn their songs in a developmental progression that is strikingly parallel to the way that humans learn the sounds that we use in speech (Doupe and Kuhl 1999). In that process, the learner imitates the sounds that he hears performed by other members of his species and relies on auditory feedback to refine his imitations of those vocalizations, and many investigations have focused on determining how and where

those complex auditory signals are processed in the songbird brain.

Electrophysiological recordings and pathway tracing studies from many research groups have revealed that activity originating in hair cells of the inner ear is propagated through a network of auditory neurons in the brainstem and thalamus and eventually reaches a forebrain area called Field L, which is the avian analog of the mammalian primary auditory cortex (Fig. 2) (reviewed in Prather 2013). From Field L, activity is passed along to secondary cortical areas including the caudal mesopallium (CM) and the caudomedial nidopallium (NCM) (Fig. 2) (Vates et al. 1996). As we ascend through that circuit, neurons become more selectively responsive to specific characteristics of those behaviorally relevant sounds (i.e., songs and calls). For example, Field L is broadly responsive to both song and a wide variety of other sounds including pure tones and white noise (Lewicki and Arthur 1996). In contrast, neurons in CM and NCM are more selectively responsive to specific aspects of auditory stimuli such as the novel or familiar status of the stimulus (Gentner and Margoliash 2003; Mello et al. 1995) and the identity of the associated individual that produced that vocalization (Menardy et al. 2012). Furthermore, immediate early gene expression within NCM is also positively correlated with the strength of song learning (Terpstra et al. 2004), suggesting that these forebrain areas may contribute to not only auditory processing but also formation and recall of memories regarding these behaviorally relevant auditory experiences.

Additional studies have also revealed highly selective auditory sites that are interconnected with CM and NCM. One of those sites is a forebrain nucleus called HVC (abbreviation used as a proper name, Fig. 2), and the auditory responses of HVC neurons are among the most selective sensory responses ever described. For example, HVC neurons respond to not only song but also more specifically to the bird's own song as opposed to songs or calls produced by members of the bird's own species (reviewed in Mooney et al. 2008). Furthermore, HVC neurons can even represent different songs in the bird's repertoire (Prather et al. 2008),

A

**Auditory Processing and Perception, Fig. 2** Auditory input is processed through an ascending neural network. In this depiction of a parasagittal section of the songbird brain, auditory input is transduced by hair cells in the cochlea and passed through the brainstem, thalamus, and eventually to auditory processing centers in the telencephalon. Areas highlighted in this text are in black font, and additional areas are shown in gray. Not all connections are shown. Arrows indicate the directionality of each connection, and gray dotted lines indicate lamina that serve as landmarks that are helpful in identifying locations in the brain. Some structures, such as HVC, are sexually

dimorphic (large in males and smaller or absent in females). Other structures, such as MLd, Field L, CM, and NCM, are robustly present in both sexes. Abbreviations are: *CM* caudal mesopallium, *Field L* auditory thalamorecipient neurons in the forebrain, *HVC* abbreviation used as a proper name, sometimes referred to as the high vocal center, *LLv* lateral lemniscus, ventral nucleus; *MLd* dorsal lateral nucleus of the mesencephalon, *NCM* caudal medial nidopallium, *Nif* nucleus interfacialis of the nidopallium, *Ov* ovoidalis, *Uva* nucleus uvulaeformis, *VTA* ventral tegmental area. (Adapted from Fig. 2 in Prather 2013)

revealing that those neurons are not simply representing classes of vocalizations (e.g., self-generated songs vs. songs performed by others). Instead, they are representing specific sounds used in vocal communication. In support of that idea, HVC neurons that respond to individual songs in the bird's own repertoire are responsive to specific elements of those songs (e.g., one specific transition between two notes), and those cells respond to playback of that element regardless of whether it was performed by the bird where that HVC cell resides or by another member of its species (Prather et al. 2008). Beyond simply responding to acoustic parameters of the song, an integrated approach combining behavioral observation and electrophysiological recording of the activity of individual HVC neurons in awake and freely behaving birds also revealed that some HVC neurons respond to not simply the acoustic properties

of auditory stimuli, but rather the animal's perception of the identity of those stimuli (Prather et al. 2009) and the syntax in which those sounds are produced (Fujimoto et al. 2011). Thus, neural activity in the songbird brain is correlated with many specific aspects of auditory processing, affording researchers many opportunities to study the neural mechanisms that underlie auditory processing and perception.

## Summary

The studies described here highlight the value of birds as a behaviorally rich and experimentally tractable context in which to continue to investigate how the brain enables auditory processing and perception. Regions of the mammalian cortex are also specialized for auditory processing, yet

our understanding remains incomplete regarding how the structure of individual neurons and the circuits they compose results in auditory perception. Cortical areas that are specialized for perception and performance of the sounds we use in speech have been identified in the human brain, yet our understanding of the functional role of those sites also remains incomplete. For example, Wernicke's area in the human brain has been implicated in our perception of the sounds that we use to communicate using language, and another region of the human brain called Broca's area has been implicated in the production of those sounds. Recent research has blurred the distinction between those brain sites, suggesting that both areas contribute to both performance and perception of the sounds that compose one of the primary ways in which we use auditory processing in our everyday lives (Flinker et al. 2015; Tremblay and Dick 2016). The obvious behavioral significance of those human brain areas highlights them as important areas for additional study, but the function of individual neurons and the circuits they compose remains challenging to detect and interpret in humans. By incorporating a blend of behavioral and neurobiological approaches, animal studies such as those performed using songbirds afford an opportunity to understand the relation between activity in specific neurons and the emergence of an organism's perception of auditory experiences.

through a medium (air, water, or a substrate), and its perception by one or more perceivers. Auditory signals are omnidirectional, can be transmitted to a large number of individuals, and can reach long distances. They are produced by a wide range of animal taxa which evolved several mechanisms for producing and perceiving sound-based signals. The use of sound for communication purposes has been reported in many mammals, birds, fishes, amphibians, insects, crustaceans, and reptiles (Bradbury and Vehrencamp 1998). Across this range, auditory signals are used in a diverse set of behavioral contexts such as mating, agonistic encounters, group coordination of movement, parent-offspring interactions, and predator avoidance.

Transmission of auditory signals can be affected by several biotic (sounds produced by other animals, including humans) and abiotic factors (vegetation, water bodies, wind, etc.). These factors can interfere, degrade, or create obstacles to sound transmission. A set of different morphological structures and behavioral strategies evolved to cope with these interferences and increase the probabilities of successful signal transmission.

## Auditory Signals

## Synonyms

Acoustic signals

## Definition

Auditory signals are animal-produced sounds that evolved via natural and sexual selection for the purpose of influencing the behavior of perceivers.

## Introduction

The auditory communication process involves signal emission by a signaler, its propagation

## Sound-Producing Mechanisms

Sound waves can be modulated at different dimensions. It can be frequency modulated (varying in pitch) or amplitude modulated (varying in loudness), and it can also vary in periodicity, the temporal pattern in which sounds are produced. This allowed for the evolution of an enormous diversity of auditory signal systems, from begging and alarm calls to birdsong and language.

Animals evolved a diverse array of specialized sound-producing structures to emit and modulate auditory signals. It is possible to classify them in two broad categories, those found in animals that breathe air actively and the ones found in animals that obtain oxygen passively (Fletcher 2007). Active air-breathing animals use the muscular control of inhaling and exhaling to force the air-flow through some kind of valve and excite a resonant flap or membrane. Animals that do not

breathe air actively need to resort to muscle-driven vibration mechanisms to produce auditory signals. A noticeable exception is the madagascar giant cockroach (*Gromphadorhina portentosa*). It emits hissing sounds that are produced by forcefully expelling air through abdominal openings called spiracles. Cicadas, some other hemipterans, and moths have a special sound-producing organ called tymbal, a drum-like ribbed membrane that can emit very loud sounds at over 100 decibels. Cicadas produce mating calls by contracting tymbal muscles which cause a series of ribs to buckle one after the other. This produces a sequence of clicks that we perceive as a buzzing sound (Young and Bennet-Clark 1995). Most insects produce sounds via stridulation, which consists of rubbing or scraping two different specialized body parts against each other, a plectrum and a file (a set of ridges). The shape and exact location of these structures can vary across different species. For example, crickets and katydids rub different parts of their wings (forewing veins and the anal wing region), while grasshoppers and locusts rub the inside of their hind legs against the forewing.

### Vocalizations: The Larynx

The mechanisms of sound production in humans are well understood and have been extended to other mammals and avian species. Notably, the source-filter theory of voice production has had a major impact on our understanding of vocal communication systems. The source-filter theory was originally proposed as a two-stage process to explain speech production in humans, but it has been generalized to approach vocal communication in nonhuman mammals and avian species (Fitch 2006). In humans and most other terrestrial mammals, auditory signals are produced by the larynx, the source, and subsequently filtered by the supralaryngeal vocal tract, the filter. The air that is expelled from the lungs and forced through the closed glottis causes oscillation of the vocal folds within the larynx, and its rate determines the fundamental frequency, also perceived as voice pitch. The sound waves produced by this oscillation travel up from the larynx and through the pharynx and oral and nasal cavities, which comprise the supralaryngeal vocal tract, to the lips and

nostrils, through which vocal sounds are radiated. In the process, the vocal tract acts as a resonator and filters the sound, attenuating certain frequencies, thus producing formant frequencies that affect our perception of voice timbre.

### Vocalizations: The Syrinx

The syrinx is the sound-producing organ of birds. It consists of a set of tympaniform membranes that vibrate as air from the lungs is forced through them. This mechanism of sound production is similar to the larynx in mammals. However, the syrinx is located further down in the trachea, close to the junction of the bronchi. The airflow coming from the lungs is modulated by the tympaniform membranes as it goes through each bronchus. The location of the tympaniform membranes varies across bird species. In most songbirds (Oscines), it is located at the medial or internal section of each bronchus, hence called medial tympaniform membranes. Songbirds employ an additional mechanism to modulate airflow. They can extend a labium opposite to the medial tympaniform membrane. These fleshy protuberances allow them to alter or even interrupt the airflow by closing each bronchial tube independently. Sound production can be controlled separately by each side of the syrinx, which allows some songbird species to produce two different sounds at the same time (Suthers and Zollinger 2004).

## Sound Detection Mechanisms

### Sound Detection in Invertebrates

Insects are the only invertebrate group in which hearing is widely used. Among different insect taxa, the skin, cartilage, and bone have been modified to serve as sound-detecting structures (Stebbins 1983). They can be categorized in antennal ears that are sensitive to the displacement of air particles and pressure-sensitive tympanal ears (Goepfert and Hennig 2016). Antennal ears are found in mosquitoes, midges, honey bees, and some flies. They are used as velocity receivers that respond to air particle movements. These movements are detected by Johnston's organ, an arrangement of densely packed mechanosensory

neurons located in the pedicel (the second segment of the antenna). In fruit flies (*Drosophila melanogaster*), different neuron subgroups in Johnston's organ respond to specific mechanical stimuli, e.g., sound vibrations, wind, and gravity.

Tympanal ears are sound-receiving eardrum-like membranes that vibrate in response to sound pressure. They have evolved independently many times in different insect orders and can be located on several parts of the body, depending on the species. For example, crickets have tympanal organs in their forelegs, while grasshoppers also have them in abdominal sections next to the thorax. Tympanal ears are composed of a tympanum, a thin cuticle that vibrates in response to pressure change; a tracheal sac, used for impedance matching between the inner side of the membrane and the external medium; and the tympanal organ, which converts mechanical vibrations into neural signals (Yager 1999).

### Sound Detection in Vertebrates

Besides some anatomical modifications such as the presence of pinnae in mammals and auditory channels joining the two ears in birds and reptiles, the general structure of the auditory system is similar across vertebrate taxa. Sound waves are guided through the ear canal to the inner ear and hit the tympanic membrane (eardrum), a small and thin membrane that separates the outer ear from the inner ear. The tympanic membrane then vibrates sympathetically with the air molecules around it. These vibrations are conveyed into the cochlea through an ossicle in the middle ear, the columella. Thus, it is possible to obtain the necessary agitation inside the cochlea, so that the hair cells of the inner ear can identify the frequencies that make up a certain sound and transmit this information to the brain in the form of electrical impulses. The cochlea has two canals, the scala vestibuli and the scala tympani, which are separated by the cochlear duct. Sound vibrations are transmitted to the cochlea through the oval window, traveling up to the scala vestibuli and returning through the scala tympani to the base and then absorbed by the round window. The scala vestibuli and the scala tympani are canals filled with fluid. This liquid fluctuates

sympathetically to variations in sound pressure received by the tympanic membrane (Bradbury and Vehrencamp 1998). The basilar membrane is a thin strip of tissue located in the cochlea. It follows the contours of the cochlea and separates the scala vestibuli from the scala tympani. It follows the coiled shell-shaped curvature of the cochlea. It becomes gradually wider as it gets further away from the base of the cochlea. The basilar membrane is covered with hair cells (hair cells at different points along the basilar membrane are sensitive to different sound frequencies) that translate sound into electrical impulses that are then transmitted to the auditory areas of the brain through the cochlear nerve.

### Sound Transmission

Sound is the result of mechanical disturbances that are transmitted to a medium as longitudinal waves. Sound waves propagate as particle compressions and rarefactions in solid, liquid, and gaseous media. The same general principles of wave propagation apply to sound waves. Because of its nature, sound cannot be polarized (as light waves), but it suffers from the action of other phenomena such as attenuation, interference, and noise. Auditory signals are structurally designed to minimize these effects and improve signal detectability.

### Sound Attenuation

Sound attenuation is the gradual decrease in the amplitude of sound waves as they propagate farther away from a sound source. This loss or dissipation of energy occurs mainly due to spherical spreading and atmospheric absorption. The magnitude of amplitude loss is proportional to the frequency of the sound wave, the higher the frequency the larger the amplitude loss. Hence, low-frequency sounds can propagate farther away than high-frequency sounds, even if they are produced at the same amplitude. Additional sound attenuation can result from other factors such as wind and temperature gradients, medium absorption, and scattering. Animals evolved different strategies to minimize the effects of sound attenuation on

auditory signals, including the use of hollow structures in the environment to amplify signals, signaling during certain times of the day when atmospheric conditions are more appropriate for long-distance sound transmission, and using redundancy in signal production to improve its detectability.

### Sound Interference and Noise

Sound interference results from the superposition of two or more sound waves. If two sound waves are produced in consonance (at the same time and at the same point), the wave amplitudes will add up, resulting in constructive interference. In contrast, if sound waves are out of phase, they cancel each other out. Small-bodied animals need to cope with a related phenomenon called acoustic short-circuiting. It happens when the sound source is smaller than the wavelength of the sound it produces. Sounds radiated from opposite edges of the body are out of phase, causing destructive interference and reducing sound pressure. Insects such as tree crickets overcome this problem by using leaves as baffles. They cut out holes in the center of leaves and calling from inside it. In this way, they effectively extend their body surface by making the sound travel to the leaf edge (Mhatre 2018).

Noise is another source of sound interference. Signal-to-noise ratio is a measurement of the amplitude of an auditory signal in a noisy environment. It compares the amplitude level of a signal with the level of background noise. The higher signal-to-noise ratio, the lower is the effect of background noise on the signal. There is some evidence that birds can shift up the frequency or increase the amplitude of songs in order to avoid interference from background noise in environments greatly affected by anthropogenic activities, such as big cities' traffic, industrial zones, airport zones, etc. (Rabin et al. 2003).

### Conclusion

The use of auditory signals is widespread across multiple taxa. Sounds can be modulated at different dimensions (frequency, amplitude, and periodicity) allowing the production of highly

complex auditory signals. A great variety of mechanisms evolved to facilitate the production, transmission, and detection of sound-based signals.

## Introduction

Autoshaping (also called sign-tracking or conditioned approach or Pavlovian conditioned approach) is a form of Pavlovian or classical conditioning. The discovery of autoshaping by Brown and Jenkins (1968) was historically significant because it showed that Pavlovian conditioned stimulus (CS)-unconditioned stimulus (US) pairings reliably induced the acquisition and maintenance of a novel type of Pavlovian conditioned response (CR). The Pavlovian autoshaping CR is a complex sequence of CS-directed, skeletal-motor responses. The autoshaping CR is reliably induced by repeated pairings of a small object (CS) with a reward (US). In the Brown and Jenkins (1968) experiment, CS-US pairings induced the pigeons to approach the keylight CS, contact the keylight CS, and peck the keylight CS. Important to the understanding of autoshaping, the food US was delivered on each trial regardless of what the pigeon did.

The discovery of autoshaping was important because complex, directed, skeletal-motor responses were widely viewed as strictly goal-directed instrumental or operant behaviors, subject to conditioning only by experience with response-reinforcer pairings (Skinner 1948). Autoshaping raised the possibility that Pavlovian skeletal-motor CRs may be induced during operant discrimination learning procedures wherein subjects experience pairings of a discrete object CS with a reward US. In this way, autoshaping CRs may be induced to then interact with operant responses in ways not previously considered.

As noted by Brown and Jenkins (1968), the induction of autoshaping CR performance is particularly likely during operant discrimination learning procedures that employ a localized reward cue. And, the use of a reward cue projected onto a small circular response key will provide the CS-US pairings conducive to the acquisition of autoshaping CR performance. Moreover, the typical operant response to obtain food reinforcement is to peck the illuminated keylight. Thus, the autoshaping CR will be pecking that is targeted at the keylight CS that also serves as the target of the operant response. Under these conditions, the

autoshaping keypecking CR is likely to develop and resemble the topography or form of the operant keypecking response.

In addition, both responses, autoshaping and operant, are directed at the same target; consequently, the autoshaping CR is likely to be “misconstrued” as an operant response. The discovery of autoshaping and the realization of the possibility of “mistaken identity” resulted in the re-evaluation of some perplexing behaviors, including positive behavioral contrast, feature-learning, misbehavior, and drug addiction.

### **The Discovery of Autoshaping: The Brown and Jenkins (1968) Experiment**

Autoshaping was first reported by Brown and Jenkins (1968). In their experiment, pigeons received 160 conditioning trials consisting of 8 s of keylight illumination (the conditioned stimulus, or CS) followed by 4 s of access to a food magazine filled with pigeon grain (the unconditioned stimulus, or US). The interval of time between each CS-US pairing trial was approximately 60 s. Presentation of the food magazine US was independent of responding and occurred on each trial regardless of what the subject did. Surprisingly, pigeons began to peck at the illuminated keylight CS even though they were not required to do so to obtain the food US. The autoshaping conditioned response (CR) resembled the unconditioned response (UR) to the presentation of the food US, which was to approach the food US, then make pecking motions directed at the food US, then perform an open-beak pecking motion to contact and consume the food US. The autoshaping CR was similar to the UR, except the action sequence of the CR was directed at the keylight CS instead of the food US. That is, after a few CS-US pairings, the pigeons began to approach the location of the keylight CS. With additional CS-US pairings, the pigeons began to make pecking motions directed at the keylight CS, and, with still further CS-US pairings, the pigeons unleashed a ballistic, keylight-directed, striking response, resulting in physical contact with the keylight CS. Their forward thrusting of the head,

in an open-beak, pecking motion made it appear as though they were attempting to “consume” the keylight CS. The topography of the autoshaping CR closely resembled the topography of the UR to the food US. This was consistent with the hypothesis that, due to CS-US pairings, the pigeons had learned to associate the keylight CS with the food US. The CS-US association hypothesis was supported by evidence that little or no keypecking was observed in control groups that received keylight illumination only (CS only), food presentation only (US only), or backward pairings (US followed by CS).

The discovery of autoshaping had an enormous impact upon investigators of basic animal learning processes, who saw, for the first time, that repeated CS-US pairings of an object CS with a reward US will reliably induce the acquisition and maintenance of Pavlovian conditioning of complex CS-directed skeletal-motor CRs. The discovery of autoshaping was totally surprising and completely unexpected. Prior to the discovery of autoshaping, responses of this sort, a complex sequence of CS-directed, skeletal-motor actions, were viewed exclusively as goal-directed instrumental or operant responses. The discovery of autoshaping complicated matters considerably, because while the autoshaping CR will have the appearance of an operant response, its behavioral characteristics will be that of an acquired Pavlovian reflex. The autoshaping CR will be cue-elicited, automatically triggered by the presentation of the CS, and involuntary, or very difficult, if not impossible, for the subject to suppress or control. These characteristics of Pavlovian CRs are in sharp contrast to the characteristics of instrumental or operant responses which are generally described as voluntary, emitted, goal-directed, intended, and skilled skeletal-motor performances.

### **Early Investigations of Autoshaping**

The discovery of autoshaping set off a flurry of research activity to establish the boundary conditions under which autoshaping CR performance was observed (for reviews, see Locurto et al.

1981; Tomie et al. 1989). The species generality of the autoshaping phenomenon was of particular interest, and with varying degrees of success, autoshaping CR performance was documented in birds (pigeons, ring doves, finches, domestic chickens, chicks, and quail), mammals (rats, mice, hamsters, guinea pigs, gerbils, horses, dogs, and cats), amphibians (frogs), reptiles (monitor lizards and turtles), fish (tilapia fish, goldfish, blue gourami, cuttlefish, sharks, halibut, and cod), nonhuman primates (cynomolgus monkeys, rhesus monkeys, and squirrel monkeys), and human beings (human children and human adults).

It should be acknowledged that the vast majority of autoshaping experiments used Pavlovian delay conditioning procedures to train pigeons or rats. Stimuli employed as the CS by investigators reporting the acquisition and maintenance of autoshaping CR performance include the brief insertion of a retractable lever, the illumination of a small cue light, a small houselight, or a small pilot light on an infusion pump, the brief insertion of a sipper tube, the presentation of a variety of small objects, including a stuffed animal, a plastic toy, a ball, a wooden coin, a live conspecific male rat, and an auditory stimulus projected from a small loudspeaker. Autoshaping has also been induced by a wide range of stimuli employed as the US. These include response-independent delivery of access to a solid food (grain pellets, mixed grains, mash), access to a sipper tube containing a liquid solution (water, saccharin, sucrose), access to a sipper tube containing a solution of an abused drug (alcohol, cocaine, chlordiazepoxide, opiates, etc.), access to warmth provided by a radiant heat source, access to brief social interaction opportunity (with a conspecific, with a sexual partner), delivery of rewarding electrical brain stimulation, and intravenous injection/infusion of drugs (cocaine, opiates, amphetamines, benzodiazepines, etc.).

### Effects of the CS-US Contingency

Early investigations of autoshaping provided compelling evidence that the acquisition and maintenance of autoshaping CR performance was reliably induced by experience with CS-US

pairings. Further experimentation revealed that more than mere CS-US pairings were required, as responding was neither acquired nor maintained, despite frequent CS-US pairings, when the food US was equally like to occur in the absence of the CS (Gamzu and Williams 1973). Thus, autoshaping is sensitive to the positive contingency between the CS and the US. That is, when the CS and the US are presented independently of one another, as in a random control procedure, then autoshaping CR performance is neither acquired nor maintained, despite the fact that, due to chance alone, the CS is sometimes followed closely in time by the US. Finally, experience with the negative CS-US contingency arrangement (i.e., presenting the US only in the absence of the CS, as for example in backward conditioning procedures or in CS-US unpaired procedures) induced the subject to withdraw from the vicinity of the CS (Wasserman et al. 1974). This response, withdrawal from the vicinity of the CS, is opposite to the CS-directed autoshaping response, to approach the vicinity of the CS, and is consistent with the view that the negative CS-US contingency induces conditioning of inhibitory CR performance (Rescorla 1968).

The initiation of the first autoshaping keypeck in the pigeon is clearly dependent upon the positive Pavlovian CS-US contingency between the illumination of the keylight CS and the presentation of the food US. But, thereafter, it is possible that the autoshaping CR may be strengthened superstitiously by the adventitious pairing of the autoshaping CR with the presentation of the food US shortly thereafter (Skinner 1948). To evaluate the possibility of superstitious conditioning, autoshaping investigators employed omission training procedures to eliminate pairings of the autoshaping CR with the food US (Williams and Williams 1969). In their experiment, pecking the keylight CS resulted in the cancellation of the food US which would have otherwise been delivered. They found that despite eliminating all keypeck-food pairings, sustained keypecking was reliably acquired in all 13 subjects, revealing that the development of autoshaping CR performance did not depend upon pairing of the keypeck CR with the food US. While the results of

omission training studies discredit an account of autoshaping based on superstition (Locurto et al. 1981), it should be noted that autoshaping is not immune to the effects of instrumental factors. For example, delay of reinforcement and the application of aversive or negative reinforcement contingencies influence the maintenance of autoshaping CR performance and do so in a manner that is consistent with an analysis based on operant reinforcement principles (Tomie et al. 1989).

### Effects of Trial Duration and Trial Spacing

The proportion of the total session time that is devoted to the presentation of the CS is highly predictive of the acquisition of autoshaping CR performance (Gibbon and Balsam 1981; Jenkins et al. 1981). When the duration of the intertrial interval (ITI) is held constant, the longer the duration of the CS, the more slowly the keypeck autoshaping CR is acquired. On the other hand, when keylight CS duration was held constant, autoshaping CR performance was initiated more quickly, requiring fewer CS-US pairing trials, with longer duration intervals separating successive CS-US pairings. According to Scalar Expectancy Theory (Gibbon and Balsam 1981), each presentation of the food US increases the associative strength of all stimuli that are present, including incidental background contextual stimuli, in direct and inverse proportion to their salience and duration, respectively. The shorter duration keylight CS accrues association with food more rapidly than does the background context. Autoshaping CR performance is elicited when the associative strength of the keylight CS, relative to the associative strength of contextual background stimuli, exceeds some threshold value. Scalar Expectancy Theory provides a formal model for deriving estimates of associative strength of a CS; moreover, it uncouples, to some extent, those factors that determine the associative strength of the CS from those that determine performance of the autoshaping CR. In addition, the model emphasizes the conditioning of contextual stimuli, which is important because the acquisition of autoshaping is profoundly retarded if the contextual stimuli have been paired with the food US (Tomie 1981). Scalar Expectancy Theory is an

example of a comparator theory of autoshaping (Miller and Schachtman 1985), which propose that autoshaping CR performance is not determined by the associative value of the keylight CS *per se* but rather by the value of the CS relative to the value of its context.

### Theoretical Implications of Autoshaping

The discovery of autoshaping showed that Pavlovian conditioning procedures, consisting of CS-US pairings, induced the acquisition and maintenance of Pavlovian CR performance of a complex sequence of directed skeletal-motor responses. This discovery contradicted the widely held view that Pavlovian conditioning procedures influenced responses that were distinct from the skilled and voluntary skeletal-motor actions of instrumental goal-directed responses. According to widely held versions of traditional twofactor theory (e.g., Rescorla and Solomon 1967), Pavlovian CRs were viewed as discrete visceral and physiological responses. Traditional Pavlovian CRs include salivary CRs, eyeblink CRs, nictitating membrane CRs, galvanic skin conductance CRs, heart rate CRs, knee-flexion CRs, etc., whose performance was mediated largely by activity of the autonomic nervous system. Furthermore, with respect to the effects of Pavlovian CRs on instrumental behaviors, Pavlovian CRs were seen primarily as emotional reactions, such as fear, which influenced the subject's motivation to perform goal-directed instrumental behaviors. For example, a tone CS for shock US elicits the conditioned fear CR, which reduces the subject's motivation to press a lever to obtain the instrumental food reinforcer. According to Two-Factor Theory, instrumental behaviors were viewed as complex sequences of peripheral motor responses that were mediated by the skeletal-motor musculature. Responses of this sort were widely regarded as subject to conditioning only by instrumental procedures. The discovery of autoshaping challenged the theoretical framework that had long served to distinguish between operant and Pavlovian responses.

Brown and Jenkins labeled this new form of Pavlovian conditioning "autoshaping," because the pigeons appeared to automatically "shape"

themselves to perform the prototypical operant key-pecking response. But the impact of autoshaping went far beyond the mere simplicity and convenience afforded by automatically shaping the performance of the operant response. The discovery of autoshaping opened the door to an expanded view of the possible ways that the Pavlovian CR may interact with instrumental responding, including the intriguing possibility of mistaken identity. That is, under some circumstances, it is entirely possible that what appears to be an instrumental response may actually be an autoshaping CR. With this in mind, it is important to note that even though autoshaping may be induced during operant reward training procedures, autoshaping CR performance is not performed to serve the instrumental purpose of acquiring the food reward US. Autoshaping that is induced during operant procedures does not increase operant goal-directed behavior. Autoshaping increases non-operant performance of operant-like responding.

### **Autoshaping and Positive Behavioral Contrast**

Positive behavioral contrast was initially reported by Reynolds (1961), who evaluated the rate at which pigeons peck the response key when the key was illuminated by a distinctive color, either red or green, that signaled the schedule of food reinforcement in effect. During non-differential training procedures, the alternating keylight colors signaled the same schedule of reinforcement, and Reynolds found that the pigeons responded at comparable rates to the red and the green keylights. When he changed the schedule in effect during the red keylight to extinction, he found that the response rate to the unchanged green keylight increased markedly, even though the rate of reinforcement during the green keylight component was unchanged.

Schwartz and Gamzu (1977) suggested that autoshaping may account for the positive behavioral contrast effect. They noted that many operant discrimination learning procedures, like those of Reynolds, provide for keypecking-contingent presentations of food reinforcement. And, in addition, food reinforcement was available for responding only in the presence of the green

keylight that was projected onto the operant response key. According to their Additivity Theory, this arrangement is conducive to the acquisition of autoshaping CR performance of green keylight CS-directed pecking, and they proposed that this autoshaping CR performance is the source of the positive behavioral contrast effect (Schwartz and Gamzu 1977). That is, the positive behavioral contrast effect, the increase in keypecking to the green keylight, is not due to the development of additional goal-directed operant keypecking, but, rather, is a case of mistaken identity. According to Additivity Theory, the effect is actually due to the acquisition of Pavlovian autoshaping keypecking CRs, which so closely resembled operant keypecks that, to the naked eye, investigators could not tell them apart. While autoshaping and additivity do not account for all instances of positive behavioral contrast (Williams 1983), it should be noted that the majority of the studies that have reported the positive behavioral contrast effect have employed conditions providing for Cue-At-Manipulandum (CAM). Tomie (1995, 1996) has noted that CAM arrangements are conducive to the development of Pavlovian autoshaping CR performance, such that the form of the autoshaping CR and the target of the autoshaping CR resemble the operant responding that induced it. According to the CAM hypothesis, the positive behavioral contrast effect is merely one example of an instance where arrangements providing for CAM may have induced autoshaping CRs that were mistaken for operant responding. A number of investigators have proposed that this type of mistaken identity may also account for characteristics of responding observed in a number of other operant procedures that provide for CAM, including studies of feature-learning (Hearst and Jenkins 1974), reports of misbehavior (Breland and Breland 1961), and symptoms of drug addiction (Flagel et al. 2009, 2017; Tomie 1995, 1996; Tomie et al. 2016; Tomie and Sharma 2013).

### **Autoshaping and Feature-Learning**

In feature-learning studies, the intrusion of autoshaping CR performance induced error-prone responding during operant discrimination

learning procedures. In a typical study, the subject responds by touching the stimulus display, which is the response manipulandum. The S+ display is a red dot on a green background. The S− display is the same, except without the red dot. This is the feature-positive discrimination, which yields excellent accuracy. The feature-negative procedure reverses the displays, so that the red dot, the distinguishing feature, is on the S−. Note that both the feature-positive and the feature-negative arrangements provide for CAM, which will induce autoshaping CR performance. Although the stimulus displays used in the two discrimination tasks are equally distinguishable from one another, subjects in the feature-negative condition make far more errors. Analysis of the location of responding supports an autoshaping interpretation of the feature-learning effect (Hearst and Jenkins 1974). Autoshaping guides feature-positive subjects to respond correctly at the red dot, but responding to the green background induces incorrect responding for feature-negative subjects. This suggests that feature-negative errors were induced by autoshaping CRs that were counted as operant responses.

### **Autoshaping and the Failure of Self-Control**

With respect to obtaining the rewarding US, the performance of the autoshaping CR is unnecessary. It serves no purpose and is a complete waste of time and energy. This is because the subject receives the rewarding US regardless of whether or not the autoshaping CR is performed. For this reason, sustained performance of the autoshaping CR is a bit odd or bizarre and may be seen as somewhat maladaptive. The performance of the autoshaping CR makes little sense because moving toward the CS typically serves to move the subject away from the location where the food US will soon be delivered. Thus, performing the autoshaping CR serves to delay the opportunity to eat the food reward US. If the subject were able to control the performance of the autoshaping CR, then the subject should simply stop doing

it. But that is not the case. Subject after subject, in experiment after experiment, perform the autoshaping CR during trial after trial, even though it gains them nothing. This indicates that the autoshaping CR is itself evidence of the failure of self-control.

As noted earlier, during omission training procedures the subject receives the food reward US only on the trials where the subject refrains from performing the autoshaping CR by not contacting the CS. This is the negative automaintenance procedure, which has generated numerous reports of the persistent maintenance of autoshaping CR performance despite the omission training contingency (for review, see Locurto et al. 1981). The negative automaintenance effect reveals that the autoshaping CR is extremely difficult for the subject to suppress and serves as the first of many demonstrations showing that the autoshaping CR is largely refractory to a wide range of its negative consequences.

For example, in long box studies (Hearst and Jenkins 1974), brief illumination of a keylight CS was paired with brief access to a tray of mixed grain (US). The pigeons began to approach and peck the keylight CS, performing the autoshaping CR, even though this removed them from the vicinity of the food US, which was available for a limited amount of time. Even though traveling from the keylight CS to the food US reduced the amount of time available to eat, subjects persisted in performing the autoshaping CR on trial after trial. Extinction of the autoshaping CR was observed only after moving the keylight CS so far away from the food trough that the pigeons could not obtain any food. When the extinguished keylight CS was illuminated, the pigeon did not run and peck it, and, as a consequence, the pigeon was able to eat the food US from the tray on that trial. This pairing of the illumination of the keylight CS with food US was sufficient to convince the pigeon to reinstate running to peck the keylight CS on subsequent trials. The long box studies reveal that the pigeons were unable to control their keypecking that was so detrimental to eating the food US, and this was the case despite their experience with eating the food US on trials where they did not engage in keypecking.

Autoshaping CR performance has been reported despite the effects of contingent shock punishment. The brief presentation of a visual cue that signals the operation of the cocaine infusion pump induces autoshaping of cue-directed approach responses. It has recently been reported that the cocaine cue is so irresistibly attractive that rats will cross an electrified grid floor to approach the location of a light cue that had previously been established as a signal for the operation of an infusion pump that delivered intravenous injections of cocaine (Saunders et al. 2013). This effect was observed even though during drug self-administration training the autoshaping response had no effect on cocaine delivery and, during the shock punishment test, the light cue was presented without infusions of cocaine. Thus, the illumination of the cue light that had previously signaled cocaine infusion “goaded” the rats into crossing the shock grid even though there was no reason for the subject to run across the electrified grid floor, other than to approach the cocaine cue light. That is, autoshaping CR performance was elicited by the light cue, despite the aversive consequence of the contingent shock punishment, and this effect was observed even though there was no drug reward for executing the response. The effect is consistent with the hypothesis that the autoshaping CR is not under the control of the subject.

The “misbehavior of organisms” was first reported by professional animal trainers who successfully applied instrumental reward training contingencies in the training of animals in a variety of tasks (Breland and Breland 1961). They did, however, experience some rather perplexing instances where things did not go according to plan. In a typical example, a raccoon was initially trained to simply pick up a wooden coin, then carry the coin to the bank, then deposit the coin into the bank, to obtain a morsel of food. While initially things went well, with further training, the raccoon began to experience problems. The raccoon seemed unable to let go of the coin. The raccoon often dipped the coin into the slot only to pull them out again. In the end, the coins were chewed, licked, scratched, clawed, rubbed, and washed, but rarely deposited.

Misbehavior is observed when formerly well-behaved subjects begin to persist in maintaining contact with the object. In the end, the raccoon was receiving a very small percentage of the available food rewards, and increasing the raccoon’s hunger drive by imposing a longer period of food deprivation prior to the training session, made matters worse. Ultimately, the trainers were forced to give up with this raccoon and start over with a new raccoon subject, only to learn that the same thing happened in raccoon after raccoon. Other abandoned projects attempted similar training with pigs, rats, squirrel monkeys, chickens, turkeys, otters, porpoises, and whales.

The misbehavior effect reveals the failure of self-control due to autoshaping CR performance that is induced by pairings of the coin CS with the food US. Autoshaping is important because it provides us with a way of understanding how behavior can become irrational and defy free will. Note that the disconnect between the raccoon’s intentions and the raccoon’s actions are not unlike those of the drug abuser, who intends to restrain drug-taking, but, instead, finds himself or herself unable to control the impulse to have yet another. In both cases, the subject is unable to control the performance of consummatory responses directed at the object that predicts reward. This suggests that the overlooked basis for the loss of control of drug-taking, the inability to terminate an ongoing drug use episode, is autoshaping of drug-taking.

## Autoshaping and Drug Addiction

Objects employed as cues that are associated with drugs of abuse elicit autoshaping responses. For example, rats will develop autoshaping CRs to small discrete object cues that are paired with cocaine, opioids, or alcohol (Carroll and Lac 1997; Tomie and Sharma 2013; Valyear et al. 2017). Incentive Sensitization Theory (IST) proposed by Robinson and Berridge (1993) suggests that autoshaping is the overt behavioral manifestation of the sensitization of incentive salience accrued to drug cues due to repeated activations of the dopamine reward pathways by abused

drugs. Consequently, drugs increasingly trigger the experience of “wanting,” which is responsible for the dramatically exaggerated motivation for drugs displayed by addicts.

There are substantial differences between individuals in their tendency to exhibit autoshaping CRs and also in their tendency to exhibit vulnerability to drug addiction. Addiction scientists have found that these tendencies covary within an individual, suggesting that autoshaping is a behavioral marker of vulnerability to drug addiction (Flagel et al. 2009; Flagel and Robinson 2017). Autoshaping procedures, consisting of repeated pairings of a discrete CS with food US, induce some rats, sign-trackers (ST), to exhibit autoshaping CR performance, while other rats, goal-trackers (GT), react to the CS by approaching the location of the food trough where the US will be delivered. When subsequently tested for self-administration of an abused drug, ST rats relative to GT rats more rapidly acquire the drug-taking response, self-administer the abused drug more frequently, and are more vulnerable to relapse to drug-taking following periods of drug abstinence. Thus, vulnerability to autoshaping confers vulnerability to drug addiction.

Those rats prone to develop autoshaping also exhibit a constellation of other addiction-like behaviors. For example, ST rats tend to be more impulsive than GT rats (Beckmann et al. 2011). ST rats also exhibit physiological traits associated with vulnerability to drug abuse (Tomie et al. 2008) as well as neurobiological markers differentially associated with drug addiction (Flagel and Robinson 2017). Therefore, addiction scientists have concluded that the tendency to perform autoshaping CRs may be the overt behavioral expression of a personality trait that confers vulnerability to drug addiction.

An alternative autoshaping account of drug addiction has also been proposed by Tomie and his associates (Tomie 1995, 1996; Tomie et al. 2008, 2016; Tomie and Sharma 2013). According to their Sign-Tracking Model of Addiction (STM), the behavioral symptoms of drug addiction, the excessive, reflexive, and involuntary drug-taking triggered by drug-associated cues, are actually autoshaping CRs that masquerade as

operant drug self-administration responses. Note that drug-taking procedures employed by humans provide for CAM, because the object employed to self-administer the drug is also a drug cue. Repeated voluntary acts of drug-taking provide pairings of the small object CS (i.e., cocktail glass, bong, tooter) with the drug’s rewarding effects. CAM arrangements induce Pavlovian autoshaping CR performance, such that the form and target of the autoshaping CR resembles the operant responding that induced it. In this way, repeated acts of drug-taking will transition voluntary drug use into the poorly controlled drug-taking of the addict. In addition, because drug-taking procedures provide for CAM, the autoshaping CR will be camouflaged to pass for operant drug self-administration, leaving the addict to complain that they were blind-sided when they try to quit and find that they can’t. STM, therefore, provides a novel theoretical account of the etiology and nosological progression from social, recreational, voluntary drug use into the realm of the excessive and poorly controlled drug-taking of the drug addict.

## Conclusion

The discovery of autoshaping in 1968 revolutionized learning theory by showing that Pavlovian CS-US pairings induced a Pavlovian CR, an acquired reflex triggered by the CS, that is described as a complex, CS-directed, skeletal-motor action sequence. Early work on autoshaping focused on establishing the robustness and generality of the phenomenon, meanwhile careful experimental analysis revealed that autoshaping was reliably induced during operant discrimination learning procedures that provided for Cue-At-Manipulandum (CAM), but were misconstrued as operant responses. More recently, addiction researchers have proposed that autoshaping provides an account of several prominent features of drug addiction. These include the user’s failure to maintain self-control of drug-taking, the user’s vulnerability to drug cues that trigger drug-taking, and the co-variation within a subject of vulnerability to autoshaping and

vulnerability to drug addiction. The emerging literature on autoshaping and drug addiction suggests that autoshaping may provide an animal learning model of the addictive personality.

## Autosome

Neelabh

Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

## Synonyms

Euchromosome; Somatic chromosome

## Definition

All chromosomes except the sex chromosomes are referred to as autosomes. They exist in pairs in the somatic cells whereas singly in the gametic cells.

## Introduction

Chromosomes can be categorized in two categories – autosomes and allosomes (sex chromosomes). All the chromosomes other than the sex chromosomes are autosomes. For example, in case of human diploid genome, 44 autosomes (22 pairs) are present along with 2 allosomes (a normal female will have a pair of X chromosome whereas a normal male will have a pair of X and Y chromosome). Autosomes have been numbered on the basis of their sizes from 1–22 in the human genome in contrast to the letters (X and Y) used for the allosomes. Genes located on these autosomes affect males and females in the same way (Ohno 2013). Another striking property of autosomes is that they are homomorphic, i.e., the position of the centromere is identical unlike the case of the male sex chromosome which is heteromorphic (Fig. 1).

The evolutionary processes in case of autosomes are fueled by homologous recombination and mutation.

**Autosome,**

**Fig. 1** Figure depicting normal human karyotype. Homomorphic nature of the autosomes and heteromorphic nature of the male sex chromosome is clearly evident from this figure (Credit: U.S. National Library of Medicine (National Library of Medicine 2017))

A

## Mapping of Autosomes

The mapping and identification of the human chromosomes is performed by extracting the chromosomes from a cell that has been arrested in the metaphase or prometaphase followed by their staining with the suitable dye (Alberts et al. 2002; Craig and Bickmore 1993). These stained chromosomes are further arranged in the standard format on the basis of their size and position of the centromere in chromosomes called as karyogram or ideogram.

The utility of this type of arrangement is that large-scale aberrations can be easily identified on comparison of the karyogram of a diseased person to that of a normal person (Therman and Susman 2012). Chromatic aberrations are the resultant of missing, extra, or irregular portion of the chromosomal DNA. Chromosomal aberration can occur in both autosomes and allosomes, but most abundantly they are found in autosomes in the form

of monosomies and trisomies ([http://anthro.palomar.edu/abnormal/abnormal\\_4.htm](http://anthro.palomar.edu/abnormal/abnormal_4.htm)).

### Monosomies

In case of a normal human being the total number of chromosomes should be 46 ( $44 + XY$  or  $44 + XX$ ). But a patient suffering from a monosomy of a particular autosome would have one copy less ( $43 + XY$  or  $43 + XX$ ) than the original chromosome number.

Cri du chat syndrome is an example of the monosomy in humans. It occurs due to the partial deletion of the end of the short p arm of chromosome number 5. The disease has been named as such because the person affected undergoes a malformed larynx which leads to distinctive cat-like voice (Niebuhr 1978).

### Trisomies

In trisomies of autosomes, one additional copy of an autosome is present ( $45 + XY$  or  $45 + XX$ ).

Down's syndrome is a very common autosomal trisomy disorder of chromosome number 21. The symptoms range from mild to moderate mental retardation along with some distinct physical traits (<https://www.cdc.gov/ncbddd/birthdefects/downsyndrome.html>). More examples are Edward's syndrome, which occurs due to the trisomy of chromosome number 18, and Patau syndrome, which occurs due to the trisomy of chromosome number 13. Apart from this, trisomy of chromosome numbers 9, 8, and 22 also occur.

## Autosomal Inheritance

The pattern of inheritance wherein transmission of alleles, present on autosomes, occurs is referred to as autosomal inheritance. This type of inheritance pattern is generally categorized into two types: autosomal dominant and autosomal recessive inheritance. In autosomal dominant disorders the mutated gene is dominant. In this condition only one copy of the mutated gene is required to be affected by the disorder. Huntington disease and Marfan syndrome follow this inheritance pattern. In autosomal recessive condition, both copies of the gene are mutated. These disorders occur when both parents are carriers. Two carriers have a 25% chance of having an unaffected child who is also a carrier and a 25% chance of having an affected child with two recessive genes. Cystic fibrosis and Sickle cell disease follow this kind of inheritance pattern. (<https://ghr.nlm.nih.gov/primer/inheritance/inheritancepatterns>).

## Conclusion

Autosomes are the chromosomes having genes for anything that is not related with sex determination. They carry genes that control somatic traits and are different from the chromosomes governing the sex determination in a lot of aspects. Each pair of autosomes is identical genetically and morphologically. Humans have 22 pairs of autosomes which are numbered from 1 to 22 depending upon their size. Chromosome 1 has approximately 2800 genes while chromosome

number 22 has around 750 genes. Mutations in the autosomal chromosomes lead to different kind aberrations like monosomies and trisomies of that particular chromosome. Furthermore, in case of mutations of the genes present on autosomes, the nature of the gene determines the pattern of inheritance that would be followed.

## Introduction

The basal ganglion in amniotes (mammals, birds, and reptiles) is a part of the forebrain telencephalon, located below or ventral to the cerebral cortex. The basal ganglia receive information about the position of the body in space and the motivational state of the animal. The basal ganglia is divided into an upper or dorsal division which underlies the control of voluntary movement and motor learning and consists of the striatum and the globus pallidus or pallidum (GP; “pale globe”), based on its appearance in brain sections. The ventral striatum (consisting of the nucleus accumbens, Ac, and olfactory tubercle, TuO) and the ventral pallidum (VP) together constitute the ventral basal ganglia, which are important for emotional and visceral functions.

A proper understanding of striatal function is only possible in context with its cellular composition and that of corticothalamic basal ganglia loops present in the amniote brain (Fig. 1). The striatum is composed mainly of inhibitory (GABAergic) medium spiny neurons (MSNs, ~7 µm in diameter),

which have numerous spines on their dendrites and project to GABAergic pallidal neurons. In mammals, excitatory (glutamatergic) neurons in the cerebral cortex project to MSNs in the striatum. “Direct pathways” are formed by projections of the striatal neurons onto the internal segment of GP (GPi). GABAergic neurons within GPi project onto excitatory thalamic neurons which project to the cortex, forming loops (cerebral cortex → striatum → GPi → thalamus → cerebral cortex) important for initiating movements. The direct pathway functions through thalamic “disinhibition” as a result of two sets of GABAergic neurons (striatal and pallidal) immediately upstream to it.

Actions of the direct pathways are opposed by “indirect” pathways also involving the striatum. These circuits consists of striatal projections to the external part of the GP (GPe), which project to the strongly excitatory subthalamic nucleus. Disinhibition of the subthalamic nucleus leads to the activation of GPi (GABAergic) which inhibits the thalamus, leading to a decrease in excitation of the motor cortex (cerebral cortex → striatum → GPe → subthalamus → GPi → thalamus → cerebral cortex). The direct and indirect pathways therefore work in concert with each other to ensure that all movements are smooth. In addition to cortical input, the striatum also receives dopaminergic projections from the substantia nigra, pars compacta, which is important for movement and learning (Kuenzel et al. 2011).

## Organization and Development of the Avian Striatal Complex

The avian basal ganglia also consist of striatal and pallidal components and are separated from the overlying cortex or “pallium” by a group of axon fibers called the lamina pallio-subpallialis (LPS). Avian striatal neurons are similar to those in mammals in that they receive projections from the pallium and dopaminergic projections from the substantia nigra. Striatal regions in all birds (vocal learners and non-learners) are similar in terms of structure, connectivity, and functions. The avian dorsal striatum underlies the processing of sensory-motor information for the production

**Avian Striatal Complex,**  
**Fig. 1** Organization of the  
 direct and indirect pathways  
 of corticothalamic basal  
 ganglion loops in amniotes

and integration of auditory, visual, and singing behaviors. This part of the striatum consists of two major subdivisions, the dorsal part of the medial striatum (MSt) and the lateral striatum (LSt). In songbirds, the song control region Area X, a specialized area dedicated to song learning as well as context-dependent singing in adulthood is located within the rostral part of MSt. A thin strip of striatum dorsal and lateral to Area X, named DsSt, is also present in rostral MSt. The dorsal striatum sends projections to the globus pallidus (GP). The ventral part of the avian striatum consists of TuO, ventral MSt, and nucleus accumbens (Ac), which are connected to the ventral pallidum (VP). The ventral basal ganglia are viscerolimbic in function, contributing mainly to food, water, sex-related reward, and motivation in appetitive behavior (Fig. 2).

During embryonic development, a structure called the basal telencephalic anlage (embryonic primordium) gives rise to the striatum and pallidum. Whereas the dorsal striatal part of the anlage gives rise to dorsal and ventral parts of striatum, its ventral part gives rise to the dorsal

and ventral parts of the pallidum. Besides these structures, the preoptic part of the anlage gives rise to the subpallial amygdala and cholinergic neurons in the basal forebrain, some of which migrate into the striatum learning (Reiner et al. 2004; Person et al. 2008; Kuenzel et al. 2011).

### Cellular Composition of the Avian Basal Ganglia

The cellular composition of both dorsal and ventral divisions of the avian striatum is almost identical to that of the mammalian striatum, in terms of morphology and histochemical and electrophysiological properties. All four main classes of striatal neurons essential for normal function are present in the medial striatum (MSt) and Area X. These include medium spiny neurons (MSNs), which are GABAergic. They also express substance P or enkephalin (neuropeptides) and DARPP32 (dopamine- and cAMP-regulated neuronal phosphoprotein). Other neuronal subtypes include fast-spiking interneurons which are

**Avian Striatal Complex, Fig. 2** Organization of neural circuits of the avian striatal complex. (Adapted and modified from Fig. 20 in Person et al. 2008)

positive for the calcium-binding protein parvalbumin, tonically active cholinergic interneurons, and low-threshold spiking interneurons which express somatostatin, neuropeptide Y, and nitric oxide synthase. Similar neurons are also present in Ac and rostral and dorsolateral TuO, which represent the ventral striatum in birds.

One of the major differences between Area X, MSt, and the mammalian dorsal striatum is the presence of pallidal neurons intermixed with MSNs throughout the medial subdivisions of the avian striatum. Components of the avian ventral striatum (Ac and TuO) are similar to their dorsal striatal counterparts in that pallidal neurons are

present throughout these regions, intermixed with MSNs and other cell types. In this regard, LSt and DsSt (also present within MSt) are similar to the mammalian striatum, since they are composed only of MSNs. Further, the mammalian dorsal striatum can be divided into “patches” or “striosomes” and the intervening “matrix.” Whereas projection neurons in the patch compartment are rich in mu-opioid receptors, they have less of acetylcholine esterase and the calcium-binding protein, calbindin, compared to the matrix. A second notable difference between the avian and mammalian striatum is the lack of the patch-and-matrix organization in the avian

striatum. Finally, cholinergic interneurons are present in MSt, Area X, and DsSt but not in LSt.

Besides the pallidal neurons which are present in Area X and MSt, the avian brain also contains a clearly demarcated globus pallidus (GP) which is reciprocally connected to the subthalamic nucleus and sends projections to the substantia nigra. As is the case for mammals, pallidal neurons are larger in size (~13  $\mu\text{m}$ ) than MSNs, are GABAergic, and contain LANT6 and parvalbumin. Pallidal neurons similar to those in mammalian GPe and GPi have been identified in the GP, ventral pallidum (VP), and deeper part of TuO in birds. The GPi neurons, which project out of the striatum, mostly express parvalbumin.

### Corticothalamic Basal Ganglia Loops in the Avian Brain and Their Functions

Neural circuits involving the avian striatum are organized in the form of corticothalamic basal ganglia pathways, as in mammals. All parts of avian striatum receive excitatory (glutamatergic) projections from the pallium and project to VTA-SNc directly or indirectly via GP and/or VP and receive dopaminergic projections from VTA-SNc complex which modulate the activity of MSNs through specialized dopaminergic receptors.

#### Medial Striatum

Among the different subdivisions of the avian striatum, the lateral part of the medial striatum (MSt) receives somatosensory, visual, auditory, and motor information from different parts of the pallium. Parts of MSt surrounding Area X in songbirds are involved in processing movement-related information (like wing-whirring and hopping) and receive multimodal input from the pallium surrounding the song control nucleus LMAN (lateral magnocellular nucleus of the anterior nidopallium), called the  $\text{LMAN}_{\text{shell}}$ . Medium spiny neurons in MSt project directly to VTA-SNc (ventral tegmental area-substantia nigra complex) and to pallidal neurons, within MSt. Collaterals of the axons of pallidal neurons in MSt project to VP and the ventromedial part of

thalamic nucleus, DLM (dorsolateral division of the medial thalamus) and to the subthalamic nucleus via VP. Further, the medial part of MSt is known to be viscerolimbic in function and receives information from the hippocampus and olfactory bulb (Feenders et al. 2008; Paterson and Bottjer 2017; Johnson et al. 1995).

#### Area X

As described above, Area X is a specialized part of the medial striatum dedicated to singing and song learning. It is a part of the anterior forebrain pathway (AFP), a neural circuit important for song learning and context-dependent singing in songbirds such as zebra finches. Medium spiny neurons (GABAergic) in Area X receive glutamatergic projections from the pallial song control regions HVC (abbreviation used as the proper name) and LMAN. The MSNs project to GABAergic GP neurons, also within Area X which project to the dorsolateral part of DLM. Since DLM projects to the central part of LMAN ( $\text{LMAN}_{\text{core}}$ ), a loop is formed within the AFP. Both HVC and LMAN also project to RA (robust nucleus of the arcopallium), a premotor nucleus which controls the movement of the syrinx through its projections to the tracheosyringeal branch of the 12th (hypoglossal) nerve. While singing, Area X receives a copy of motor command from HVC, which is modified by the AFP to generate variability and matched to innate song template learnt by juvenile birds during the sensitive period for song learning. This ability to generate variable songs is a form of learning by trial and error, which helps young songbirds produce and practice their songs, which become adult-like over time (Kubikova et al. 2007).

Area X is also linked to circuits important for the motivation to sing and context-dependent singing through its projections to VP, which in turn projects to VTA-SNc. When juvenile birds sing in the presence of their fathers or when adult males sing to females, higher levels of dopamine are released into Area X by the VTA-SNc than when birds sing alone. Interestingly, the medial part of Area X appears to be important for the production of female-directed song, whereas the lateral part of this nucleus appears to be important

for singing undirected song, in adult male zebra finches. Additionally, Area X also controls acoustic properties of songs such as its frequency, pitch, or length of song syllables via its connections to LMAN (Sasaki et al. 2006).

### Dorsal Strip of Striatum

Besides Area X, the “dorsal strip” (DsSt) appears to be present exclusively in songbirds. Medium spiny neurons in this region project directly to VTA-SNc and also indirectly, through their projections to VP. However, the functions of this region have not been identified so far.

### Lateral Striatum

Besides the movement-related and song-related functions of the medial striatum, the lateral striatum (LSt) is a part of both direct and indirect pathways. As a part of a direct pathway, MSNs in this region receive input from somatic pallial regions and project to SNr (substantia nigra, pars reticulata) and GP. Pallidal neurons further project to the avian motor thalamic nucleus (ventrointermediate area or VIA), which innervate the motor pallium in the Wulst or hyperpallium. Since striatal LSt neurons also project to the avian subthalamic nucleus via the GP, LSt forms part of an indirect pathway similar to that in mammals. In addition to its somato-motor functions, LSt receives input from the entopallium (E), which is a part of the tectofugal visual system and therefore plays a role in processing visual information. In terms of its cellular composition, a unique feature of LSt is that it is the only part of avian striatum which does not have either cholinergic interneurons or pallidal neurons.

### Olfactory Tubercles

The olfactory bulb, hippocampus, piriform cortex, and areas of the brain related to the autonomic nervous system project to the superficial (striatal) part of TuO, which further projects to pallidal neurons within the same region. Based on the fact that these neurons innervate the hypothalamus, TuO appears to be important for integrating olfactory, limbic, and visceral information.

### Nucleus Accumbens

The avian nucleus accumbens is located in rostral ventromedial MSt and is important for motivated goal-directed behavior, reward mechanisms, and emotions. It receives input from several brain regions including the hippocampus, septum, piriform cortex, caudal VP, and arcopallium. As in mammals, the avian Ac forms a “limbic loop” consisting of projections from the medial pallium (similar to the prefrontal cortex) which innervate Ac. Nucleus accumbens may be involved in learning and memory through its connections to VP which projects to the avian counterpart of the dorsomedial thalamic nucleus, which is known to be involved in these functions (Bálint and Csillag 2007).

## Avoidance

Ruth M. Colwill  
Brown University, Providence, RI, USA

## Synonyms

Discriminated avoidance; Free-operant avoidance; Sidman avoidance; Signaled avoidance

## Definition

Behavior that prevents or postpones exposure to an anticipated aversive stimulus or threat.

## Introduction

Avoidance is an adaptive and versatile defensive behavior that helps protect many taxa from engaging with dangerous situations and harmful stimuli. In the wild, prey may seek refuge when an alarm call is heard or flee if the scent of a predator is detected, thus eluding a potentially fatal encounter or serious injury. Avoidance is distinct from escape, which refers to behavior that terminates an ongoing exposure to an aversive stimulus or threat. The roles of learning, fear, and anxiety in avoidance behavior have been the focus of laboratory research for many decades. This interest arose in part from the puzzle that avoidance behavior posed for theories of reinforcement: What is the reward for a behavior that is followed by a nonevent? It has persisted because of the insights that animal models of avoidance behavior can contribute to our understanding and treatment of human psychopathologies including generalized anxiety disorder, hoarding, obsessive-compulsive disorder, post-traumatic stress disorder, social anxiety disorder, and phobias.

## Avoidance Is Ubiquitous in Nature

Avoidance is used by wild animals to minimize predation risk while foraging, searching for mates, or procuring other resources. Whereas predator escape behaviors are predominantly innate, having evolved through the process of natural selection, predator avoidance behavior can be acquired or fine-tuned through learning. Life experiences provide a rich supply of opportunities for animals to gather temporal, spatial, and sensory information that can be used to avert hazardous encounters with predators. Decisions about when or where to forage are influenced by perceived predation risk in a diversity of prey, including termitophagous ants (*Pheidole titanus*), fathead minnows (*Pimephales promelas*), dark-eyed juncos (*Junco hyemalis*), herons (*Ardeidae*), larval tiger salamanders (*Ambystoma tigrinum*), Anolis lizards (*Anolis Sagrei*), Merriam's kangaroo rats (*Dipodomys merriami*), caribou (*Rangifer tarandus*), African buffalo (*Syncerus caffer*) and

elk (*Cervus elaphus*). With knowledge of the relative prevalence of aerial, aquatic, and terrestrial predators, mallard ducks, for example, can adjust time spent in shallow or deep water or on land. Similarly, learning to identify the referential meaning of different alarm calls enables individuals to deploy predator-appropriate defensive strategies without needing to locate the specific threat. Such use of referential specificity in alarm calls has been demonstrated in several avian and mammalian species, including chickens (*Gallus gallus*), Japanese great tits (*Parus major minor*), Siberian jays (*Perisoreus infaustus*), Gunnison's prairie dogs (*Cynomys gunnisoni*), meerkats (*Suricata suricatta*), Campbell's monkeys (*Cercopithecus campbelli*), Diana monkeys (*Cercopithecus diana*), ring-tailed lemurs (*Lemur catta*) and vervet monkeys (*Chlorocebus pygerrhus*).

Learning about the temporal and spatial patterns of predators and the meaning of alarm calls likely involves Pavlovian conditioning. This conditioning process may also play a role in learning about predator-related cues such as scents, sounds, and appearance. In such cases, the survival of captive bred animals released into the wild can be improved by predatory threat exposures prior to their release. A separate learning process, instrumental conditioning, may also influence avoidance behavior depending on the consequences of that behavior. The potential contributions of these two learning processes to avoidance behavior have long been the focus of intense theoretical and empirical analysis.

## Avoidance in the Laboratory

The study of avoidance behavior has occupied a central role in the history of learning theory. The major problem confronting researchers was to explain the emergence and persistence of a behavior for which there was no tangible reinforcement. This issue directed much of the empirical research. Theories of avoidance behavior that emerged from this tradition have typically conceded that both Pavlovian and instrumental conditioning processes are involved.

## Avoidance Procedures

The standard procedures for the experimental analysis of avoidance behavior are discrete trial signaled (discriminated) avoidance and free-operant (Sidman) avoidance with mild electric shock as the aversive stimulus. Using these two methods, successful avoidance has been demonstrated in fish, birds, and mammals, including humans.

In a typical signaled avoidance task, a trial is initiated by a warning stimulus (WS). What happens next depends on what the subject does. If the designated avoidance response occurs within a predetermined interval following onset of the WS, the WS is turned off and no shock is delivered. The subject has successfully avoided the shock. If this deadline is missed, shock is turned on. As soon as the designated response occurs, both the WS and the shock are turned off. The subject has successfully escaped the shock.

In a typical free-operant avoidance task, brief shocks are scheduled to occur at a specific rate (the shock-shock interval); the designated avoidance response extends that interval by canceling or postponing the upcoming scheduled shock (the response-shock interval). Robust avoidance is obtained when the response-shock interval is longer than the shock-shock interval. Timing is critical for this task as only temporal information can be used to predict shock delivery.

## Nature of the Avoidance Response

Some avoidance responses are readily acquired whereas others are not. In rats, for example, jumping over a hurdle to avoid shock can be established in just a few trials. Pressing a lever to avoid shock, however, can take many hundreds of trials and performance is not as robust. This variability in acquisition and consistency among avoidance responses has been attributed by some researchers to variations in interference from either innate behaviors or Pavlovian conditioned responses (CRs). For example, Bolles (1970) pointed to differences in the compatibility of the designated avoidance response with the animal's innate defensive responses to danger. He argued that evolutionary adaptation to predators had equipped animals with species-specific defense

reactions (SSDRs) to danger. Rats, he alleged, might freeze, flee or fight depending on details of the threat. Thus, if the avoidance response was part of the animal's normal repertoire of defensive behavior, acquisition was rapid; if not, acquisition was poor and unreliable. The predatory imminence hypothesis expands further on the ecological and evolutionary effects on avoidance behavior (Fanselow and Lester 1988).

### The Instrumental Contingency

There is little doubt that an animal's biology can exercise considerable influence on avoidance behavior in the laboratory. However, evidence that avoidance behavior can be affected by its consequences suggests that appeal to SSDRs or CRs alone is not sufficient to understand all aspects of avoidance behavior (Mackintosh 1983).

In one of the earliest studies to hint at the critical role of the instrumental contingency between the avoidance response and the aversive consequences, Brogden et al. (1938) trained some guinea pigs to run inside a wheel to avoid shock. After only a few days, they performed perfectly. Whenever the WS came on, these subjects turned the wheel and avoided the scheduled shock. The importance of the response consequences was demonstrated by the comparatively inferior performance of a second group of guinea pigs trained with a purely Pavlovian contingency. For these subjects, shock always occurred 2 s after the WS came on regardless of their behavior. Running in the wheel was never reliably established in these animals even after many days of training.

### The Role of Escape in Avoidance Behavior

Escape responses were once considered indispensable to avoidance behavior. According to this view, reinforcement could only occur on escape trials when the response successfully terminated or removed the aversive event. This account made two strong predictions: escape and avoidance responses had to be identical and response extinction should occur on avoidance trials. Neither of these predictions was confirmed. Studies have shown, for example, that animals can learn to make one response to escape shock and a

different response to avoid shock (Mowrer and Lamoreaux 1946). Solving the avoidance puzzle, that is how a nonevent can strengthen a response, came to dominate research on avoidance.

## Theories of Avoidance

Theoretical analyses of avoidance have considered three fundamentally distinct solutions to the avoidance puzzle: avoidance behavior is reinforced by fear reduction; avoidance behavior is self-reinforcing; avoidance behavior is determined by response expectancies.

### Fear Reduction

Two factor theory accounts for avoidance behavior through an interaction of Pavlovian and instrumental conditioning. Briefly, fear is conditioned to the WS on escape trials when it is paired with shock. This is the Pavlovian conditioning process. Now, there can be a reduction in fear on avoidance trials when the WS is turned off by the designated response. This reduction in conditioned fear serves to reinforce or strengthen the connection between the WS and the avoidance response. This is the classical stimulus-response (S-R) instrumental conditioning process. Turning off the WS on an avoidance trial has the same effect as turning off the shock on an escape trial; behavior is reinforced by a reduction in fear and thus becomes more likely to be elicited by that situation in the future (Mowrer and Lamoreaux 1946).

Assessment of two factor theory largely focused on its predictions about the relationship between fear of the WS and strength of the avoidance response and the necessity of terminating the WS after the designated response has occurred. The results of such studies have suggested a more complicated picture. Fear of the WS is not a simple function of response strength and WS termination is critical for training some responses but not others. The popularity of two factor theory, however, has not been entirely diminished by these findings or by contemporary theoretical developments regarding the goal-directed nature of instrumental behavior.

### Reinforcement Through Conditioned Inhibition

The major alternative to two factor avoidance theory employs the concept of conditioned inhibition of fear (Rescorla 1968). Building on evidence that a stimulus which predicts the omission of an expected aversive event becomes a conditioned inhibitor of fear, researchers proposed that internal stimuli correlated with performance of the avoidance response similarly acquire inhibitory properties. According to this view, the WS provides an expectation of shock through Pavlovian conditioning on escape trials; on avoidance trials, the WS in conjunction with the response is followed by the omission of the expected shock and a period of safety. This discrimination establishes the response feedback stimuli as conditioned inhibitors of fear (safety signals) which function to strengthen avoidance responding through positive reinforcement. In this way, avoidance behavior can be viewed as self-reinforcing.

Consistent with this analysis, studies have shown that arranging for the avoidance response to be accompanied by an external stimulus establishes that stimulus as a conditioned inhibitor of fear (Rescorla 1968). In addition, explicit safety signals enhance avoidance responding even if the WS is not terminated on avoidance trials. This analysis helps address the persistent nature of avoidance behavior because the reward value of safety signals derives from their status as conditioned inhibitors, which are known to be immune to the effects of simple extinction.

### Response Expectancies

Expectancy theory is classified as a cognitive account of avoidance. It asserts that two expectancies are learned: that shock will occur if the designated response is not made and that no shock will occur if the designated response is made. The decision to respond is based on a conscious appraisal of this information. Lovibond (2006) has been a forceful proponent of expectancy theory in its application to human avoidance behavior.

Observations consistent with this view include the persistent nature of avoidance responding, the

effects of response prevention, and the decoupling between response strength, and fear of the WS with extended training. However, results of recent studies manipulating outcome expectancies after initial training and failing to find appropriate changes in avoidance behavior have challenged this approach.

### Current Directions in Avoidance Research

Maladaptive avoidance is recognized as a significant component of many clinical pathologies in human behavior. Efforts to improve cognitive, behavioral, and pharmacological therapies have catalyzed a renewed interest in theories of avoidance behavior and the underlying neurobiological mechanisms (Krypotos et al. 2015; LeDoux et al. 2016). These endeavors are complemented by research using relatively new model systems. A number of escape and avoidance assays have been developed for use with larval and adult zebrafish (Colwill and Creton 2011). For example, just 1 week after fertilization, free-swimming zebrafish larvae imaged in multiwell plates show avoidance of computer-generated moving visual stimuli as well as dark or open areas. With its tractable genetics and rapid development, the zebrafish provides opportunities to study mechanisms involved in the development of fear and anxiety disorders and to screen novel pharmaceutical compounds with therapeutic potential.

### Conclusion

Avoidance behavior is likely to be determined by a confluence of factors including innate dispositions in reactions to threats, learning about cues predictive of danger and safety, and effects arising from response consequences and repetition. Maladaptive avoidance behavior in humans may represent abnormal functioning of one or more components of a complex system designed to protect an individual from harm.

## Definition

A long specialized structure of a neuron that conducts an electrical signal from the cell body to the axon terminals.

## Introduction

Axons are a long specialized structure of the neuron that conducts an electrical signal from the cell body to the terminals. Axons play an integral role in neural communication, as they allow nerve impulses to travel to neurons, muscles, and glands around the brain and body. They are essential in the propagation of an action potential as their unique structural properties allow for the efficient conduction of electrical signals. When signals are received by the dendrites, they are collected at the axon hillock, a structure adjacent to the cell body. If the combined signal is strong enough, it will trigger an action potential. The axon has a unique

cytoskeletal structure that is essential to the life of the neuron as it is used to transport important materials back and forth the cell. A prominent characteristic of an axon is the presence of a myelin sheath, which serves to insulate the structure and hasten propagation. Faster conduction velocity afforded by myelin allows for quicker neural processing, which helps all aspects of functioning, like fine motor movements. As such, up to 90% of cerebral neurons are myelinated. Given the importance of the axon, damage caused by injury, disease, and trauma can lead to neuronal death and a number of conditions that affect the nervous system.

## Structure and Function

The axon stems from a neuron's cell body and serves to transmit signals to the terminals (Fig. 1a). Adjacent to the cell body is the initial segment of the axon, also known as the axon hillock. This area collects the signals from the cell body and is the point of action potential initiation. It features a high density of voltage-gated sodium ion channels (Fig. 1b) that make the area

more excitable and facilitate the initiation of an action potential (Wollner and Catterall 1986). Further down, the axon features a collection of voltage-gated ion channels along its membrane that open when a reversal in the neuron's charge occurs. In unmyelinated neurons, these ion channels are dispersed evenly across the cell, while ion channels in myelinated neurons are concentrated at high densities at the gaps between myelin (Fig. 1b), also called the nodes of Ranvier (Squire et al. 2008).

Axons, as a whole, get their structure from a cytoskeleton that contains microtubules and neurofilaments. In the axon, all microtubules are arranged from the soma to the terminals in a plus-end-out formation. This indicates that the positive side of the microtubule is away from the cell body. This critical formation differs from that of the dendrites, which have microtubules arranged in both directions. Another important function of the axon is to transport materials, such as nutrients, growth factors, and neurotransmitters, back and forth from the cell body. Along the axonal microtubule, dynein and kinesin are two primary proteins used for active transport of vesicles. Dynein moves to the minus end, towards the soma, while most

**Axon, Fig. 1** Structure of a neuron. (a) General structure of multipolar neuron containing the axon hillock, axon, myelin, nodes of Ranvier and axon terminals. (b) Close-up of node of Ranvier showing the accumulation of ion channels

kinesin move toward the axon terminals (Lodish et al. 2000a). While microtubules work to elongate the axon, neurofilaments are arranged radially and determine the diameter. Axons contain more neurofilaments as they increase in diameter (Lobsiger and Cleveland 2009). This is an important characteristic as larger diameter axons feature faster action potentials (Salami et al. 2003).

## Development

Much of a neuron's function comes from its polarity, which influences the development of the axon. In a developing neuron, small projections, called neurites, grow out of the cell body. In a multipolar cell, one neurite grows into an axon while others grow into dendrites. This development occurs as a result of signaling pathways triggered by extrinsic and intrinsic signals. Extrinsic signals are secreted by neurons into the extracellular environment, while intrinsic signals remain inside the cell and are modulated by the expression of a gene. UNC-6 is a protein found in the extracellular environment that guides the direction in which an axon grows. Neurotrophins, another extrinsic factor, bind to the cell and trigger a series of events that enhance the formation of the axon. Intrinsic signals, such as Ras and PI3K, trigger biochemical cascades that cause conformational changes in the arrangement of microtubules and neurofilaments. Knocking out these protein-producing genes leads to the inhibition of axonal formation, while overexpression leads to the development of multiple axons. Both intrinsic and extrinsic signals are necessary for the proper polarization of a neuron (Arimura and Kaibuchi 2007).

## Role in Action Potential

The axon plays an important role in the propagation of an action potential. In order to propagate the signal, the axon relies on several aspects of its structure. The inside of a neuron is negative relative to the outside due to the cell's permeability and availability of ions inside and outside of the cell. An action potential usually begins at the axon

hillock when the combined afferent signal becomes strong enough to cause a reversal in charge. However, a neuron can also receive signals and initiate an action potential by receiving input directly to the axon. This is known as an axo-axonic synapse. There are two main ion channels, sodium and potassium, that are present along the axon and serve to depolarize and repolarize the cell, respectively. Due to the slow activation of the potassium ion channel, these processes do not occur at the same time. As the cell depolarizes, the current travels down the axon and activates more ion channels, propagating the signal down the axon. (Lodish et al. 2000b).

## Myelination

Myelination is paramount to proper neural functioning, as it allows an electrical signal to propagate more quickly. (Salami et al. 2003). Myelin works by insulating an action potential as it is pulled by the concentration and electrostatic gradients. The signal travels down the axon by a process called saltatory conduction, where it jumps between the gaps of myelinated segments. These gaps, called nodes of Ranvier, contain a high concentration of voltage-gated ion channels that allow the action potential to quickly regenerate (Salzer 1997). Axons become myelinated with the help of glial cells within the body. These supporting cells, including oligodendrocytes and Schwann cells, myelinate axons within the central and peripheral nervous systems, respectively. When myelin is lost, the electrical charge traveling down an axon slows down. This loss of conduction velocity, and subsequent slower processing, results in various neurocognitive diseases such as multiple sclerosis (Squire et al. 2008).

## Deterioration in Injury and Disease

Due to the brain's complexity, axonal injury can result in a myriad of neurological impairments, especially in densely configured myelinated axons. Axons can be damaged in many ways, including traumatic brain injury (TBI) and disease. Common in TBI, diffuse axonal injury

(DAI) is characterized as damage to the axon or its structure, including disconnection from the cell body or microtubule breakage. Injury occurs as the rapid acceleration and deceleration of the brain puts a large strain on the axon cytoskeleton. Damage following DAI results in a cascade of events leading to the degeneration and eventual death of a neuron, including interrupted axonal transport and disorganized neurofilaments (Tang-Schomer et al. 2010). Pathology associated with TBI arises in the form of poorer cognitive processing and memory formation. Alzheimer's dementia (AD) is a common form of disease-driven axonal deterioration. In AD, axonal damage arises from the buildup of plaques and tangles that disrupt normal cellular function, usually in structures associated with learning and memory. In AD, Tau proteins dissociate from the microtubule, causing their breakdown and neuronal death. Furthermore, the loose Tau proteins bundle and form tangles that can strangle other neurons (Mattson 2004). In both injury and disease, axonal transport is interrupted and can lead to the death of the cell, highlighting the importance of an axon to the overall health of the neuron.

## B.F. Skinner

Wendy A. Williams  
Department of Psychology, Central Washington  
University, Ellensburg, WA, USA

### Introduction

Burriss Frederick Skinner (March 20, 1904–August 18, 1990), also known as B. F. Skinner, was an American research psychologist, radical behaviorist, social commentator, and writer. He is considered the father of operant conditioning and modern behavior analysis. He was the Edgar Pierce Professor of Psychology at Harvard University from 1958 until his retirement in 1974. He received the Citation for Outstanding Lifetime Contribution to Psychology from the American Psychological Association shortly before his death in 1990. He is considered the foremost eminent psychologist of the twentieth century (Haggbloom et al. 2002). He published 19 books, and nearly 200 journal articles. He received honorary degrees from over 20 universities worldwide (B. F. Skinner Foundation 2016a). During his lifetime, he would receive dozens of major awards for his work (see Table 1).

### Biography

B. F. Skinner was born in Susquehanna, Pennsylvania, in 1904. His father was a lawyer, and his mother was a housewife. As a youngster, he had a penchant for building things. But by high school, he had developed a love of literature and writing. He later attended Hamilton College in Clinton, New York, where he majored in English. He never felt that he fit in at Hamilton. He wasn't particularly good at sports. He resented the chapel attendance requirement and was a self-admitted troublemaker. Following graduation from Hamilton in May of 1926, Skinner spent 2 years as a writer (rather unsuccessfully). Then, at age 24, he enrolled at Harvard University to study psychology (Skinner 1976).

### Harvard University (1928–1936)

Early in his graduate school career, Skinner was influenced by a number of important individuals including Charles Darwin, E. L. Thorndike, and especially, John B. Watson, whose *Psychology as the Behaviorist View It* (1913) advocated for an empirical science of behavior and rejected both Wundt's introspective methods and the elaborate psycho-analytic theories of Freud and Jung. Skinner embraced Watson's behavioristic philosophy that rejected explanations based on a

metaphorical science of the “mind” including mental states, beliefs, memory, or goals. Like Watson, Skinner rejected the “mind” as a useful scientific construct, and he argued that the goal of any science of behavior was to predict and control

behavior through an analysis of the interaction between the organism the current stimulus environment.

At Harvard, Skinner found a mentor in psychology department chair William Crozier,

a physiologist interested in sensation and perception. Crozier was committed to laboratory experimentation using intact organisms. He believed that only through experimental control could a clear understanding of behavior emerge. He also rejected current popular beliefs that ascribed cause to internal states (B. F. Skinner Foundation 2016b). It was in Crozier's lab that Skinner was allowed to develop his own research program focused on the influence of environmental contingencies on behavior. Skinner was afforded great freedom at Harvard under the direction of Crozier. He spent much of his time alone in the laboratory "doing exactly as I pleased," studying the behavior of rats (B. F. Skinner Foundation 2016b).

**Inventions.** With his fundamental engineering skills and a healthy dose of trial and error, he fashioned the first conditioning chamber (See Fig. 1) and the cumulative recorder, a seismograph-like device for recording individual responses as a function of time (slope indicates the rate of responding). The recorder revealed the unique effects different behavioral contingencies had on response rates and response patterns (See Fig. 2).

**Operant Conditioning.** Skinner's work at Harvard rejected the current line of behavioristic thinking, based on the work of Pavlov and Watson, that all behavior is reflexive, elicited by the stimuli that precede it (S-R theory). Rather,

Skinner argued for a different type of behavior – voluntary behavior that is instrumental in changing the surrounding environment. Skinner coined the term *operant* and defined it as any non-reflexive behavior that operates on the environment. Furthermore, he showed that various arrangements of consequences in time directly influenced response strength, likelihood, and probability differently. He called this new kind of learning "*operant conditioning*," aka instrumental conditioning (See "► [Instrumental Learning](#)", "► [Operant Conditioning](#)").

Using his uniquely engineered equipment, Skinner systematically and comprehensively, investigated the effects of environmental consequences on behavior. Studying rats in experiments that strictly controlled the consequences of behavior, he painstakingly outlined the effects of positive reinforcement and extinction on the rate of lever pressing. He developed alternative laws for these operant behaviors, including the laws of reinforcement and instrumental extinction. He addressed the development of the conditional nature of discriminative stimuli as excitatory or inhibitory occasion setters. The foundations for his later famous three-term contingency (antecedent->behavior->consequence) were laid at this time. This seminal work, *The Behavior of Organisms*, was published in 1938.

## The Minnesota Years

After completing his doctoral degree at Harvard University in 1931, where he remained as a research associate until 1936, Skinner accepted a professorial position at the University of Minnesota in Minneapolis and remained there through 1945. While there, he conducted his top secret "Pigeons in a Pelican" study in an attempt to contribute to the war effort. With \$25,000 in funding from the National Research Defense Committee, Skinner successfully trained pigeons to peck at a target as the primary missile guidance system in simulated military warheads (Stromberg, 2011). In tests, the pigeons provided a reliable guidance system even when descending

**B.F. Skinner, Fig. 2** The main components of a cumulative recorder. Paper is driven at a constant rate (e.g., 2.4 min/in.); each response moves a pen a fixed distance (aka tic) across the paper in real time. When the pen reached the top of the page (1100 responses), it resets automatically. Response rates are measured as responses per minute. Slope indicates response rate (e.g., a slope of  $45^\circ =$  about 45 responses per min). (This graphic is reproduced from Catania 2017)

rapidly, and even when surrounded by loud warlike noises (B. F. Skinner Foundation 2016b). The project was discontinued when another federally funded, secret missile guidance system based on radar was deemed more viable. This unique project is described in detail in Skinner's book *Cumulative Record* (1959).

## The Harvard Years

In 1945, Skinner accepted the position of Chair of the Psychology Department at Indiana University in Bloomington, Indiana. He remained there only 2 years. The field of behavior analysis was growing rapidly and in 1947, he was offered the William James Lecturer position at Harvard University, where he remained for the rest of his academic career. In 1948, the Harvard Pigeon Laboratory was established and remained an active research laboratory for the next 50 years (Heyman 2002). Under Skinner's leadership (and later under both Skinner and Richard J. Herrnstein), the lab produced some of the most productive behavioral psychologists of the twentieth century (for a list of his graduate students, see Baum 2002). Many of these renown and respected psychologists provided their own insights and reminiscences about their time in the Harvard pigeon lab in 2002 in a retrospective

issue of the *Journal of the Experimental Analysis of Behavior* (Lattal 2002).

According to Skinner and Herrnstein's former students, life in the Harvard pigeon Lab was the most formative time in their lives, marked by great intellectual growth and experimental freedom (for a comprehensive overview of life in and the impact of the Harvard pigeon lab see Azrin 2002; Baum 2002; Belke 2002; Boakes 2002; Catania 2002; Dews 2002; Fantino 2002; Ferster 2002; Gollub 2002; Green 2002; Heyman 2002; Himeline 2002; Lattal 2002; Lindsley 2002; Logue 2002; MacSweeney 2002; Miller 2002; Morse and Dews 2002; Staddon 2002; Zuriff 2002).

**Schedules of Reinforcement.** In 1950, Skinner began what is considered by many to be his biggest contribution to the study of behavior. Together with research fellow Charles Ferster, they began what would be 5 years of intense laboratory work dedicated to a comprehensive analysis of the nature of different schedules of reinforcement (Ferster 2002; Morse and Dews 2002). What emerged was evidence that uniquely scheduled contingencies of reinforcement produced distinctive and observable patterns of responding. For example, when the number of responses required for reinforcement was fixed (aka fixed-ratio schedule), a stereotyped (step-function) pattern of responding emerged. Similarly, if the delay before a response would

produce reinforcement was held constant (aka fixed-interval schedule), a different response pattern (scallops) emerged. But when the response requirements varied and were unpredictable (as with variable-ratio and variable-interval schedules), response patterns became more regular and stable.

A detailed compendium outlining simple and complex schedule effects was published as *Schedules of Reinforcement* in 1957 (Ferster and Skinner 1957) (See “► [Instrumental Conditioning](#)”, “► [Operant Conditioning](#)”, “► [Schedules of Reinforcement](#)”).

**Schedules of Reinforcement and Foraging Research.** The operant conditioning chamber and complex schedules of reinforcement (e.g., chain schedules, multiple schedules, mixed schedules, tandem schedules, and random ratio schedules) provided the groundwork for detailed laboratory analyses of the factors that influence foraging-related choice behavior. Psychologists adapted operant conditioning-chamber procedures to simulate the contingencies imposed by the various phases of the foraging process.

Searching, choice, handling, and consumption could be isolated and manipulated independently allowing for excellent experimental control.

In 1979, Lea developed an operant analogue of foraging designed to mimic foraging-related choices in an operant conditioning chamber (See Fig. 3). Pigeons searched by pecking on a white key programmed on a fixed interval schedule. Upon completion of the search phase, the second key was illuminated either Red or Green. This was the Choice Phase. A single response to the colored key turned off the white search key and committed the bird to either a FI 5-sec or FI-20 sec response requirement representing two different Handling Phases (aka 2 different prey items requiring different amounts of effort or time to obtain). Alternatively, three responses on the white Search key reinstated the next search phase; in this way, the bird could reject the Red FI 5-sec or Green FI 20-sec alternative. Completion of the handling requirement produced 2.5 sec of food. After food delivery, the next search phase began.

Lea manipulated search duration to test foraging selectivity as a function of prey density. Lea

**B.F. Skinner,**  
**Fig. 3** Flowchart of the foraging procedure developed by Lea (1979). Rectangles represent the different foraging phases. Circles represent the response keys in the operant chamber. Pigeons responded on either of 2 keys throughout the experiment. Key color changes represent shifts between the various phases. Response contingencies for each phase are noted. (Lea 1979)

found that acceptance of the FI 20-sec option increased with longer searches. With short searches, birds rejected the less-preferred option (FI 20-sec) often; with longer search times, the birds exhibited greater indifference between the two choice options.

However, he also found that preference did not track predictions based on simple optimality theory (E/T); it did not produce a sudden step-function change in preference from one schedule to the other. Instead the birds perseverated on the preferred (FI-5) alternative beyond the point where optimality theory (see “► [Optimal Foraging Theory](#)”) dictated a change to the less preferred schedule.

Lea's (1979) results prompted questions about this persistent impulsivity and the gradual nature of preference change. Moreover, similarities between Lea's procedure and the more common concurrent-chains procedure in psychology operant labs were noted. Abarca and Fantino (1982) observed that Lea's handling phases were analogous to the terminal links of concurrent chains. Impulsive biases had been previously noted using FI schedules in the concurrent chain procedure. Abarca and Fantino replicated Lea's study, replacing the FI schedules with variable interval (VI) schedules (considerably more appropriate for simulating actual handling). The probability of either alternative was set to 50%. Search time was varied from a FI 4-sec schedule to a FI 63-sec schedule. They too found that preference for the less-preferred option increased with increases in search time. Again, the preference shift was gradual and delayed, not abrupt as predicted by optimality theory.

In a second experiment, Abarca and Fantino (1982) also changed the FI in the search phase to a VI (also a more realistic simulation of searching). Again, they found the same relationship between search time and acceptance of the less-preferred alternative. The similarity between Lea's procedure and the more common, and well-studied concurrent chains procedure opened the door for psychological explanations of the persistent impulsivity observed in both sets of experiments. In particular, Herrnstein's matching law (1961), Baum's (1974) generalized matching law and

Fantino's delay reduction hypothesis provided insights into the observed asymmetry of choice in foraging situations.

Of particular interest, the delay-reduction hypothesis (now theory) introduced a new commodity, other than just energy as a function of time, that is influential in foraging-related choice: namely, conditioned reinforcement – the ability of cues that signal primary reinforcement to influence choice. More of a psychological commodity, animals' sensitivity to reductions in expected delays to reinforcement highlights the importance of schedules of reinforcement in the discovery of a deeper and more complex understanding of foraging-related choice. In particular, Fantino's delay reduction theory serves as an example of the ongoing impact of Skinner's early work with schedules of reinforcement on the modern study of animal behavior. (For additional contributions of operant conditioning to the study of foraging-related choice, see Abarca et al. 1985; Baum 1983; Fantino 1987; Fantino and Abarca 2010; Shettleworth 1988; Williams and Fantino 1994.)

**Superstition in the Pigeon.** In his famous study, Skinner (1947) explained how accidental reinforcement could lead to the development of idiosyncratic behaviors. He argued that response-reinforcer contingencies are nothing more than coincidental, albeit reliable, instances of immediate positive reinforcement. In an effort to demonstrate the power of temporal contiguity, he presented food to eight hungry pigeons every 15 sec. In six of the eight cases, the birds developed highly stereotyped behaviors. From head bobbing to turning in circles, each of the six birds developed its own “superstitious” response pattern. To further demonstrate the strength of these responses, he placed them on extinction (see ► [“Extinction in Learning”](#)). It took over 10,000 responses for the behaviors to cease. Skinner drew comparisons between the birds' behavior and the development of superstitious behavior in humans (e.g., the behavior of bowlers as the ball approaches the end of the alley). He argued that their appearance was merely the results of “accidental correlations” between behavior and presentations of the reinforcer.

In an attempt to further explore Skinner's findings, Staddon and Simmelhag (1971) replicated Skinner's study but examined the resulting behavior in greater detail. They found that although idiosyncratic behaviors emerged early in the interval, the behaviors at the end of the interval were dominated by only a few species-typical response patterns associated with foraging and feeding (e.g., looking at the food cup; pecking near the food cup). They called the early behaviors *interim responses* and suggested that they reflected other sources of reinforcement. The late behaviors (which were much more uniform across birds) were labeled *terminal behaviors*.

In 1985, Timberlake and Lucas returned to the famous superstition studies to investigate the nature of the interim behaviors more thoroughly. They conducted nine separate experiments. Their findings suggested that early, idiosyncratic behaviors simply reflect earlier phases in the foraging sequence such as searching (e.g., head bobbing and circling). They proposed that a behavior systems approach would explain the increases in certain types of behaviors. By presenting food, the feeding system is triggered, increasing a collection of organized feeding-related behaviors. These food-related behaviors become more likely in general and may stretch from the beginning to the end of a short interval in a manner that simulates more naturalistic foraging tendencies (see "► Behavior Systems").

The long history associated with Skinner's superstition study highlights the relevance, the impact, and the importance of Skinner's early work. The breadth of his experimentation and theoretical work has provided a basis for continued investigation for decades.

## Radical Behaviorism

Skinner considered himself a behaviorist, influenced by such traditional behaviorist figures as E. L. Thorndike, Ivan Pavlov, and John B. Watson. However, his approach differed from those of his predecessors. He called himself a "radical behaviorist" because of his departure from the popular Pavlovian/Watsonian S-R

theories of the time. Sometimes interpreted as a type of logical positivism, Skinner clarified his radical behaviorism by saying:

... some versions of logical positivism ruled private events out of bounds because there could be no public agreement about their validity. Introspection could not be accepted as a scientific practice, and the psychology of people like Wilhelm Wundt and Edward B. Titchener was attacked accordingly. Radical behaviorism, however, takes a different line. . . . Radical behaviorism restores some kind of balance. It does not insist upon truth by agreement and can therefore consider events taking place in the private world within the skin. It does not call these events unobservable, and it does not dismiss them as subjective. It simply questions the nature of the object observed and the reliability of the observations. (Skinner 1974)

It was Skinner's belief that the study of behavior is a natural science that firmly places environmental influence as the major determinant of complex behavior in both human and nonhuman animals. His radical behaviorism promoted the idea that the powerful influence of the environment on behavior should be the emphasis of modern psychology. According to Skinner, radical behaviorism would always be responsible for explaining all behavior, public and private, and that strong empirical evidence of environmental influence would be required to offset mentalistic accounts of behavior (Skinner 1974).

Skinner acknowledged the role of physiology and confidently expected the field of physiology to provide a complete accounting of the internal processes associated with all behavior. In 2004, Morris, Lazo, & Smith published a comprehensive review article in which they evaluated Skinner's own writings for evidence of his discussion of biological participation (aka genetics, physiology, and evolution) in operant learning. Their paper was intended to address criticisms that Skinner denied or dismissed the role of biological processes in learning and behavior. They found that Skinner addressed biological participation in 97 of his 289 primary source publications, stretching across his 61-year publishing career. In his 1988 book chapter, *Genes and Behavior*, Skinner concludes that a complete understanding of behavior would require a synthesis of genetic, behavioral, and cultural influence (see "► Behaviorism").

## From Darwin to Selection by Consequences

Perhaps the most detailed treatise of the developmental relationship stretching from the publication of Charles Darwin's *Origin of Species* to the behaviorism that launched Skinner's early work is offered by Boakes' (1984) *From Darwin to Behaviorism: Psychology and the Minds of Animals*. Boakes, a product of the Harvard pigeon lab himself, outlines the transitions of evolutionary nobility, from Darwin to Romanes to Lloyd Morgan. Throughout those early years, a growing reliance on comparative psychology, direct observation, and empirical evidence gradually led to people like James, Wundt, Helmholtz, and Thorndike. Their emphasis on laboratory research, combined with American university administrative and economic influences produced a nationwide academic growth spurt that favored animal psychology (Baum 1985; Boakes 1984). It was in this climate that J. B. Watson was empowered to write his famous manifesto (1913), arguing against introspection as a scientifically valid method, and insisting that the goals for psychology be redefined as the prediction and control of behavior. It was in this context that Skinner's radical behaviorism emerged.

In 1981, Skinner published a telling article in the journal *Science*, where he outlined his theory of selection by consequences and clearly established the origins of his overarching principles of operant conditioning as coming from the earlier concept of natural selection. In it, he argued that the ability of behavioral consequences to differentially select one behavior over another had begun in the primordial soup with the evolution of powerful laws that govern the relationships between organism and environment. Citing traditional natural selection as the first selection mechanism, Skinner suggested a second kind of selection: one that operates at the level of the individual and that evolved in parallel with natural selection (see "► [Natural Selection](#)").

Skinner (1981) outlined the selective properties of operant conditioning and their importance to the individual (as opposed to the species as a whole). Adaptation, he argued, involves both

species level and individual-level selection mechanisms. He explained that adaptation at the behavioral level often occurs before the mechanism of natural selection has the chance to exert species-level selection. According to Skinner, the individual that adapts behaviorally has less need for an innate repertoire. In that way, "operant conditioning could not only supplement the natural selection of behavior, it could replace it." He went on to explain how selection by consequences could build on an organism's susceptibilities to the reinforcing properties of food and sexual behavior, and how selection by consequences opens the door to new forms of behavior. Despite his controversial claims, it is clear from Skinner's own thesis that his connection to the foundations of animal behavior is forged. The synthesis of Darwin's evolutionary theory and B. F. Skinner's selection by consequences ensures the operant conditioning and Dr. Skinner himself will continue to have an important and relevant place in the history of the study of animal behavior.

## Back-Test

Christina Meier  
University of Manitoba, Winnipeg, MB, Canada

## Synonyms

n-back task

## Procedure

The back-test, or n-back task, is commonly used to assess working memory. Subjects performing this task are presented with a continuous series of stimuli (e.g., sounds or spoken words, visual images, spatial locations, odors, etc.) and required to respond in a certain way when the currently presented stimulus is identical to the one presented  $n$  items previously in the series. For example, in a 2-back task, the response is required for any item that is the same as the one presented two items earlier. Tasks usually range from 1-back to 3-back versions with 4-back and 5-back tasks being rarer; a 0-back control version in which subjects have to respond every time a specific target appears (regardless of whether or when it had appeared earlier in the series) may also be administered, often to assess baseline performance in neuroimaging studies.

## Application

As such, the n-back task, developed by Kirchner (1958), primarily tests a subject's ability to protect working memory contents from interference from competing or external stimuli (Barch and Smith 2008) – though critical analyses have pointed out that performance on the n-back task may depend on “familiarity- and recognition-based discrimination processes” rather than active memory recall (Jaeggi et al. 2010). It has applications mainly in clinical and cognitive neuroscience research with humans but has also been claimed, alongside other paradigms such as complex span-tests, to be a useful training tool to improve working memory performance and general intelligence (Jaeggi et al. 2008; Au et al. 2015).

## Animal Versions

Despite its popularity as an assessment tool for human working memory capacity, the n-back task has not yet been picked up by researchers interested in studying animal working memory. Only recently has the search begun to develop a version of the n-back task that can be used with animals,

primarily to facilitate the development of animal models of working memory and subsequently their use in the assessment and treatment of memory impairments (Dudchenko et al. 2013). The most notable efforts have been made by Ko and Evenden (2009), who developed an operant version for rodents, although they reported some difficulties regarding training rodents to learn the task demands in the 2-back version.

Outside of the operant box, paradigms that might be considered conceptually related to conventional n-back tasks are those that focused on animals' memory of sequentially presented stimuli (such as locations, objects, odors, etc.). In most of these paradigms (though there are continuous variations as well, see Kesner et al. 2001), subjects are initially presented with a sequence of stimuli, followed by a forced-choice test between a pair of probe stimuli – allowing the experimenters to test the subject's recollection of whether a stimulus had appeared earlier or later in the sequence (e.g., Chiba et al. 1997; DeVito and Eichenbaum 2011). Though these tasks do not require the subject to actively indicate whether a stimulus had previously appeared at a specific position in the sequence relative to the currently presented stimulus, as the n-back task does, they do allow an assessment of whether the perceived stimuli are encoded in a sequential order. There is additional evidence that this discrimination ability is not simply a result of recent exposure: DeVito and Eichenbaum (2011) demonstrated that their rodents were capable of forming distinct representations of the internal order of separate sequences, as they did not discriminate between pairs of stimuli from different sequences.

[Basal cognition](#); [Unicellular cognition](#)

## Definition

Cognition in this context is defined as the complex of sensory and other information-processing mechanisms an organism has for becoming

familiar, valuing, and interacting with features of its environment in order to meet existential needs, the most basic of which are survival/persistence, growth/thriving, and reproduction.

## Introduction

The idea that single-celled organisms, such as bacteria, display cognition is highly controversial, although the notion has had scientific advocates since the early twentieth century. As the tools to observe, study, and challenge the behavior of microbes have improved dramatically over the past few decades, the number of scientists ascribing cognition to phylogenetically basal organisms is slowly growing. Those who endorse the idea tend to be influenced by the surprising genomic and molecular similarities among diverse kinds of organisms. They also tend to be concerned with tracing the origin and evolution of the biological function of cognition and the molecular mechanisms that underpin cognition in animals, both with and without nervous systems, as well as in plants. On this account, the inference that biological cognition is more rather than less coextensive with cellular life is easily drawn.

## Two Approaches to Cognition

There are, broadly speaking, two approaches to the study of animal cognition (Lyon 2006). The first and most common approach is to characterize some feature of human cognition and then look for and analyze apparent correlates in other animals. Examples include the **mirror self-recognition** test, which is designed to detect self-awareness in nonhuman animals; most animal experiments for studying **theory of mind**, an animal's ability to infer what another animal might be thinking; and most animal experiments for studying **imitation**. These and other tests are based on the human experience of cognition. The second approach to animal cognition begins with the facts of biology – what it takes for an organism to make a living – and extrapolates from these the kind of function cognition might be. This

approach treats cognition as a biological function like other biological functions (e.g., respiration, digestion), albeit one of special interest, particularly in its more complex forms.

The former, which takes the human case as its starting point and has long dominated comparative psychology (see, e.g., Shettleworth 1993), has been called the *anthropogenic approach* to cognition because it arises from (has its *genesis* in) human beings (*anthropos*) (Lyon 2006). The latter, which takes biology as its starting point, is the *biogenic approach* to cognition; it arises from (has its *genesis* in) the living state (*bios*) rather than in a particular animal species. Both approaches are necessary for a complete understanding of human cognition, and, in particular, for identifying animal models of different human cognitive capacities that cannot be explored in human subjects for ethical reasons.

From an anthropogenic standpoint, however, bacterial cognition makes very little sense. As a result, bacterial *chemotaxis*, the directed movement of a cell toward or away from a chemical gradient, has long served as an example of readily anthropomorphized, non-cognitive behavior (e.g., Dennett 1987). Some microbiologists have even dismissed the idea of cognitive-seeming bacterial behavior as an anthropomorphic fantasy (Redfield 2002). By contrast, from a biogenic standpoint, which is grounded in the reality of evolution and the requirements of surviving, growing, and reproducing in an unpredictable world, the possibility of bacterial cognition is less easily dismissed. Thus, increasing numbers of neuroscientists have pointed to microbes for an evolutionary origin story for the aspects of cognition that they study (e.g., Allman 1999; Damasio 1999; Greenspan 2007; Sterling and Laughlin 2015).

This entry is written from a biogenic point of view. It does not assume that continuity necessarily exists between the behavior-generating capacities of unicellular organisms and highly complex cognitive traits such as self-awareness, metacognition, theory of mind, and the capacity to imitate. However, it does assume a degree of continuity with those basic behavior-generating capacities normally considered cognitive in multicellular animals, including humans.

## Bacterial Cognition and Scientific Opinion

Darwin's intuition that all forms of life share certain (unspecified) basic features, which organisms differ in "degree but not kind" along both physical and mental dimensions of their existence (Darwin 1874/1909), remains controversial but has deep scientific roots, not merely philosophical/religious ones. Aristotle, the founder of European life science (Lennox 2001), sets out the earliest systematic account – beginning with plants – of what the Greeks called *psuche* (psyche), an untranslatable term that combines features of vitality and mind (Nussbaum and Putnam 1992). Antonie van Leeuwenhoek, the seventeenth-century Dutch lens maker who was the first to study the microbial world, famously gave the name *animalcules* (tiny animals) to the single-celled organisms whose behavior he observed through his microscopes. In the modern era, Herbert Spencer appears to be the first psychologist to suggest that mind and life have a similar tendency, "the continuous adjustment of internal relations to external relations" (Spencer 1855; p. 374) and that this similarity has important implications for the study of mind.

Debates about the Darwinian proposition began in earnest in the early twentieth century. One pole of the empirical debate was exemplified by physiologist Jacques Loeb, who argued that animal behavior is for the most part mechanical, reflex-like, innate, purely physiological, and therefore non-cognitive (Loeb 1900). At the opposite pole of the empirical debate was zoologist H.S. Jennings, considered the founder of mathematical genetics, whose microscopic observations of bacterial and protist behavior convinced him of the basic soundness of Darwin's intuition about continuity (Jennings 1905/1962). The most influential US textbook on comparative psychology of the early twentieth century, *The Animal Mind* by Margaret Floy Washburn (Washburn 1936), includes an entire chapter on amoeba. Washburn, the first woman to be awarded a PhD in psychology, cites Jennings' work extensively but leaves open the question of whether amoebae have "mind." This largely was due to

the intimate linkage of mind with consciousness, a nexus that James B. Watson's **behaviorism**, which was heavily influenced by Loeb, was explicitly designed to sever (Watson 1913).

Although there were always discontents (e.g., Von Uexküll 1926), behaviorism of one form or another became the dominant theoretical approach in comparative psychology and animal ethology during the twentieth century (Greenspan and Baars 2005). It arguably still is, if much less so. In essence, behaviorism assumes the reflex concept covers most behavioral contingencies in animals. "Bacterial behavior" (to say nothing of plant behavior) was regarded by many as verging on an oxymoron. All that changed with the investigation of bacterial chemotaxis by three US research teams, headed by Julius Adler at the University of Wisconsin/Madison, Howard Berg at Harvard University, and Daniel Koshland Jr at the University of California, Berkeley.

Adler's laboratory made the study of bacterial chemotaxis possible, starting in the early 1960s, by developing (1) an objective assay to establish that bacteria are actually capable of movement (not simply drifting); (2) growth media that enabled bacterial movement and/or promoted the synthesis of *flagella*, whip-like molecular motors that propel the cell; and, finally, (3) an assay for bacterial chemotaxis (Adler 2011). Genetic studies led to chemotactic knockout mutants, which greatly advanced the research. By 1965, unpublished news of the lab's discoveries led to Adler being invited to speak about bacterial chemotaxis at a Cold Spring Harbor symposium on "Sensory Receptors" in animals, an invitation most would have considered at best highly improbable and most likely inconceivable. The following year "Chemotaxis in Bacteria" (Adler 1966), the seminal article in the field, was published in *Science*.

Adler's lab demonstrated that the common gut bacterium *Escherichia coli* is both positively and negatively chemotactic; it is attracted, or will move toward, some chemical stimuli, and is repelled by, or will move away from, others. This movement is enabled by changes in the methylation state of binding sites on proteins called *chemoreceptors* that sense different

chemicals, and combinations of chemicals, in the environment. Adler's lab also discovered that bacteria "make decisions" when faced with conflicting information, meaning their behavior choices are based (like many animals') on non-linear calculations, not straightforward linear summations of the available information on positive and negative states of affairs (Adler and Tso 1974).

First at Colorado, then at Harvard, Berg and colleagues invented and progressively refined a microscope to track bacterial behavior in three dimensions (Berg and Brown 1972), which enabled progress on understanding the molecular mechanics of bacterial chemotaxis. At Berkeley, Koshland's lab discovered that bacteria possess a form of memory (Macnab and Koshland 1972); correctly hypothesized the general process by which signals are transduced within the cell, from environment to flagellum (Koshland 1977), the molecular logic of which was later found to be quite general, including in animals, and demonstrated how these responses in bacteria can be fine-tuned by mechanisms also known to operate in animals, such as habituation (adaptation) and sensitization (amplification) (Koshland et al. 1982).

Meanwhile, without regard to the findings described above, Chilean neurobiologist Humberto Maturana, co-author of one of the seminal papers in early neuroscience (Lettvin et al. 1959), was working through the implications of a novel, highly abstract but internally coherent framework for conceiving the biological function of cognition (Maturana 1970; Lyon 2004), which he concluded must apply to bacteria as well as to animals with nervous systems. *The Biology of Cognition* would not be widely available for another decade. Contemporaneously, Koshland published a monograph advancing an argument that bacterial chemotaxis could provide a productive model for animal behavior generally, including neurally driven human behavior (Koshland 1980).

However, Maturana's and Koshland's theoretical work appears not to have much effect on microbiology specifically or biology generally, to say nothing of neurobiology. When scientists

rediscovered the possibility of something like cognition in bacteria, "minimal" or otherwise, they more or less reinvented the wheel based on more recent findings and different theoretical concerns. These include bacteriologists Klaas Hellingwerf (Hellingwerf et al. 1995), Joseph Lengeler (Lengeler et al. 2000), and James Shapiro (2007); computational biologist Dennis Bray (2009); and biochemist Jeffry Stock (Stock et al. 2002; Baker and Stock 2007).

## Bacteria and the Cognitive Toolkit

The idea that a "toolkit" of behavior-generating processes and capacities exists that comprises what we ordinarily call the biological function of cognition was proposed more than two decades ago by philosopher Peter Godfrey-Smith (1996). While he did not precisely specify the contents of the toolkit, the human psychological literature provides many suggestions (e.g., Rathus 2016): sensing and acting; memory and learning; anticipation and prediction; assessing value (often grouped under emotion and motivation); integrating multiple sources of information and making decisions about risk and reward under various degrees of uncertainty; and communication. Table 1 sets out one possible version of a cognitive toolkit of basic cognitive capacities defined from a biogenic standpoint (Lyon 2015). Needless to say, the toolkit was derived from the human case in the first instance and forms the basis of much comparative psychological investigation, past and present, between and among different types of animals.

*E. coli* exhibits all of these capacities. As stated above, it has been known for decades that the bacterium possesses memory, displays valenced behavior, and makes decisions in the face of conflicting information based on poorly understood nonlinear dynamics, which still cannot be predicted. Moreover, it is now known that *E. coli* possesses complex arrays of chemoreceptors, numbering in the thousands, which are individually responsive to combinations (even within one protein) of multiple different sources of chemical information (Porter et al. 2011). These protein

**Bacteria, Table 1** A basic toolkit of cognitive capacities. (Adapted from Lyon 2015)

| Basic cognitive toolkit (functions/capacities) |                                                                                                                                                                                                                                   |
|------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Sensing/perception                             | The capacity to sense and recognize (re-cognize) existentially salient features of the internal and surrounding milieu                                                                                                            |
| Memory                                         | The capacity to retain information about the immediate (and possibly distant) past and to calibrate the sensorium to take account of this information (e.g., via signal amplification)                                            |
| Valence                                        | The capacity of an organism to assign a value (positive, negative, neutral) to the summary of information about its surroundings at a given moment, relative to its own current state                                             |
| Decision-making (signal integration)           | The capacity to combine information from multiple sources, because all known organisms to date appear to be capable of sensing more than one thing                                                                                |
| Behavior                                       | The capacity of an organism to adapt via changing its spatial, structural, or functional relation to its external or internal milieu                                                                                              |
| Error detection                                | The capacity of an organism to determine whether a behavior has succeeded or failed                                                                                                                                               |
| Learning                                       | The capacity to adapt behavior to existentially salient stimuli according to past experience by altering the threshold for response                                                                                               |
| Anticipation                                   | The capacity to predict what is likely to happen next based on an early stimulus                                                                                                                                                  |
| Communication                                  | The capacity to interact productively with other organisms, notably (but not limited to) conspecifics, including initiating collective action, which may or may not include an explicit means of differentiating “us” from “them” |

arrays, dubbed “nanobrain” by some, are capable of highly complex computations (Stock et al. 2002) and appear to function as “neural networks” or “integrated circuits” in bacteria with flagella (Hellinger et al. 1995; Baker and Stock 2007; Bray 2009).

*E. coli* also has been shown to exhibit anticipatory behavior; it can predict what is likely to happen next when presented with particular information, such as a certain increase in ambient temperature (Tagkopoulos et al. 2008). This anticipatory behavior can be changed by conditioning or associative learning (Mitchell et al. 2009). It is currently assumed that this form of associative learning takes place at a population-level over generations via epigenetic mechanisms, but it is already well-demonstrated that *E. coli* possesses nonassociative types of learning shared with vertebrates, such as habituation and sensitization. For a discussion of bacterial communication, see the section on Sociality below.

Finally, despite the above, it is worth noting that *E. coli* is not particularly well-endowed in terms of the kinds of signal transduction systems associated with more complex behaviors in the bacterial world (Lyon 2017). These systems include two-component systems, chemotactic systems, and extra-cytoplasmic alternative sigma factors, the latter of which are environmentally

sensitive transcription factors believed to expand a bacterium’s response repertoire under challenging, and possibly novel, conditions (Pinto and Mascher 2016). In short, *E. coli* is not the smartest bacterium on the block, but it does not have to be; it is not developmentally complex.

**Sociality, Communication, and Development: Ratchets for Complexity**

The idea that most bacteria live not as solitary individuals but in large groups or multicellular consortia called *biofilms* is now widely accepted, although its discovery is relatively recent (Shapiro and Dworkin 1997). *Sociomicrobiology*, proposed 12 years ago as the study of microbial social behavior, including the degree to which it is determined by nature (genetics) or nurture (development, behavior), is now a mainstream concept (Whiteley et al. 2017). As is the case with social animals, the more dependent on coordinated behavior the bacterial species is, the more complex its behavior tends to be, and the richer its endowment of potentially cognitive mechanisms (Lyon 2017). The most complex behaviors of which bacteria are capable – such as coordinated predation, bioluminescence, social motility, nutrient scavenging and distribution, developmental

sequences leading to sporulation, and synthesis of virulence factors – are performed by multicellular aggregates of individual cells responding to chemical or physical signals that serve as forms of communication.

The most commonly known form of bacterial communication goes by two interchangeable labels: autoinduction and quorum sensing (Miller and Bassler 2001). *Autoinduction*, the original term of art, was introduced because the phenomenon involves a cell's own synthesis, export, and subsequent detection of particular molecules, which bring about a significant, energetically costly change in the cell's genetic expression (in some cases, the expression of hundreds of genes) and, thereby, its physiology. In short, the cell produces molecules (autoinducers) that induce a change in itself (autoinduction) that affects its subsequent survival, growth, or reproduction. *Quorum sensing* was introduced when it became apparent that autoinduction is a means by which a cell determines that it is in a sufficiently large population at which a change in physiology is energetically advantageous. A single cell acting alone – to synthesize a virulence factor, say, or bioluminescence – is not only ineffective but also highly vulnerable. If an insufficient number of conspecifics are in the vicinity, the quorum sensing molecules diffuse away from the cell, and nothing happens. If there are large numbers of cells nearby, the autoinducers aggregate and are detected by the cell. A change in the structure or function of the cell is induced when a threshold is reached.

The autocrine and paracrine activity of quorum sensing molecules has been compared favorably to the activity of hormones in multicellular animals and plants (Sperandio et al. 2003), and some have speculated that autoinducing peptides may be the prototypes, if not the precursors, of neuropeptides. At the time of writing, eight different types of bacterial quorum sensing signal had been identified (Whiteley et al. 2017). In general, Gram-negative bacteria primarily synthesize acyl homoserine lactones (AHLs) for quorum sensing, while Gram-positive bacteria often use oligopeptides. However, some bacterial species are capable of synthesizing both types, and

several species have been identified that operate two or more different quorum sensing systems (Bassler and Losick 2006).

*Myxococcus xanthus*, a rod-shaped soil-dwelling predator with a highly complex life cycle, uses three chemically distinct intercellular signals in the developmental sequence leading to the formation of spore-filled fruiting bodies under conditions of nutrient decline (Lloyd and Whitworth 2017). Fruiting body formation is a dramatic behavior involving massive aggregations that have been likened to the mass animal migrations of the central African plains (Shimkets 1999). Cooperative “wolf packs” of *M. xanthus* hunt other bacteria, archaea, and fungi. Because they are much slower-moving than their prey, *M. xanthus* secrete molecular products to attract, for example, *E. coli* (Shi and Zusman 1993). Recently *M. xanthus* also has been shown to respond to AHL-based quorum sensing molecules produced by other bacteria as indicators of potential prey. AHLs, which *M. xanthus* cannot synthesize, nevertheless appear to enhance myxobacterial motility, stimulate predation, retard sporulation, and promote germination of myxospores (Lloyd and Whitworth 2017). Please note: the autoinducers are not in themselves nutritive for *M. xanthus*; the bacteria that produce them are.

Some bacteria also use physical signals – notably electricity generated by membrane-embedded ion channels – to communicate quickly over long distances in environments where diffusion is ineffective (Prindle et al. 2015). As is well-known, ion channels are critical to the transmission of information by neurons. Bacterial ion channels long served as models for understanding how neuronal ion channels operate, even as their function in microbes remained obscure. A recent series of experiments demonstrated that *Bacillus subtilis* uses electricity generated by ion channels to send signals across a biofilm, from the center to the periphery (Prindle et al. 2015). As the colony grows, the distance between the founder population and the periphery increases, making it difficult for nutrients to diffuse across the numerous layers of cells to the center. Meanwhile, the population at the “eating edge” of the periphery is able

to feed so long as nutrients are available. When the cells at the center begin to starve, they generate electrical impulses that propagate to the peripheral cells, which stop feeding, allowing nutrients to diffuse to the core. A “resume” signal is sent when nutritional homeostasis is restored. The important point is that *B. subtilis* (at least) uses ion channels to generate electrical signals for the same reason neurons do: to transmit information rapidly over significant distances comprised of intervening cells.

It is now widely accepted that signaling-mediated aggregative behavior of individual cells in the domain of prokaryotes (bacteria and archaea) as well as in eukaryotes (amoeba, protists, fungi) was a critical step in the evolution of multicellular animal life (Kaiser 2001). There is now a growing body of evidence to suggest that bacterial signal transduction and motility, the autocrine and paracrine activities of quorum sensing molecules within cell populations, and the neuron-like electrical signaling of bacterial ion channels may have played a more direct role in the evolution of animal cognition.

## Conclusion

The idea of bacterial cognition significantly expands the possibilities for understanding the biological function and evolution of cognition more generally, by introducing to cognitive science the methods that have brought the greatest progress in other areas of biology, particularly at the level of molecules, genetics, genomes, and development. The study of bacterial behavior makes it conceivable to connect the dots – the real continuities as well as the obvious discontinuities – across not only the prokaryote-eukaryote divide but also across the transitions from unicellular to multicellular life and from nonneural behavior to the origin and evolution of nervous systems.

Some may object: Why call it “cognition”? The only reasonable response, given the almost unimaginable scientific advances of the past two decades, is: Why not? There is *no scientific consensus about what cognition is* and where it is to be

found on the tree of life. None. Arguably, this is the result of keeping one eye firmly on *Homo sapiens* whenever cognition is studied. In turn the anthropogenic tendency, which implicitly dictates an overriding emphasis on human brain structure, has only served artificially to distance cognitive science from the rest of biology, and thus stymied attempts at the kind of generalization that has facilitated rapid advances elsewhere in the life sciences. From a biogenic standpoint, the costs of this practice now clearly outweigh the benefits.

Obviously, bacteria are not at all like humans. Bacterial cells are orders of magnitude smaller than the smallest human cell, the red blood cell. Size should be irrelevant for understanding cognition as a biological function, however. What counts, at least from the standpoint of the biogenic approach to cognition, is whether the behavior-generating capacities exhibited by bacteria system fit comfortably within a toolbox of capacities typically considered cognitive in more complex organisms and whether the mechanisms that generate these capacities in bacteria can shed light on cognitive capacities in other organisms.

## Definition

Balanced polymorphism or balancing selection is a phenomenon by which more than one morph

exists in the population at a stable frequency at a given time.

## Introduction

Polymorphism refers to the occurrence of two or more forms of phenotypes in a population. Balanced polymorphism occurs in a population when alleles exist in a population in stable frequencies due to selection. The term balanced polymorphism was coined by an ecological geneticist F.B. Ford (1901–1988). The superiority of heterozygotes over the homozygotes allows the maintenance of balanced polymorphism in population. This **heterozygote superiority** is also referred as **overdominance** or **single locus heterosis**. Under balanced polymorphism, there is neither the fixation of alleles nor the elimination of alleles. If the heterozygote of any mutation is fitter than the mutant homozygote and confers an adaptive advantage, then the mutation is maintained at an intermediate, balanced frequency rather than being fixed (Sellis et al. 2011). According to Dobzhansky and Pavlovsky (1960), if the heterozygotes for a pair of alleles,  $A_1A_2$ , are possessing adaptive value greater than the corresponding poorly adapted homozygotes,  $A_1A_1$  and  $A_2A_2$  then in sexually reproducing and cross-fertilizing populations, natural selection will establish an equilibrium state at which the two alleles,  $A_1$  and  $A_2$ , will continue to occur in the population with certain frequencies. Other possible sources other than heterozygote advantage through which the balancing selection is maintained in the population are negative frequency-dependent selection as well as temporal or spatial heterogeneous selection (Hedrick 2012).

## Examples of Balanced Polymorphism

Most of the alleles for which balanced polymorphism is maintained in the human population are associated with certain disease or pathogen resistance. One of the classic examples of balanced polymorphism in the human population is sickle cell gene polymorphism. **Sickle cell disease** is caused by the single nucleotide mutation of the  $\beta$  globin gene, thus causing production of abnormal

hemoglobin resulting into sickle shape like red blood cells. The sickle-shaped red blood cells are fragile and clog the blood vessels thus causing damage to organs, severe anemia, as well as heart failure. Heterozygous carriers ( $\text{Hb}^A/\text{Hb}^S$ ) of sickle cell trait in a population possess mixture of both normal erythrocytes having normal hemoglobin and sickle-shaped cells, while homozygous carriers ( $\text{Hb}^S/\text{Hb}^S$ ) of sickle cell gene in the population have greater proportion of sickle cells in blood. Despite the deleterious character of homozygotes, the sickle mutation exists in human population since the heterozygotes possess selective advantage of being malaria resistant. This was firstly confirmed by the work of A.C Allison (Allison 1954), linking heterozygotes to protection from malaria in Ugandans. Hence, in area where malaria is prevalent, sickle cell heterozygotes will survive more and tend to increase the frequency of sickle cell gene over normal homozygotes ( $\text{Hb}^A/\text{Hb}^A$ ) as they are more susceptible to malaria. Therefore, sickle cell trait shows a case of balanced polymorphism where advantageous heterozygotes coexist with disadvantageous homozygotes in a population. In addition to this, there are also several other hematological diseases which are maintained in population as a result of balanced polymorphism such as **glucose-6-phosphate dehydrogenase deficiency,  $\beta$ -thalassemia, and ovalocytosis** in which the homozygote hemoglobinopathy is balanced by the heterozygote advantage of protection from malaria.

Another potential example of balanced polymorphism involves **Tay–Sachs disease** conferring advantage to heterozygotes from tuberculosis. Tay–Sachs disease is an autosomal recessive genetic disorder mostly occurring in children's due to mutation in HEXA gene, situated on chromosome 15. HEXA gene codes for enzyme hexosaminidase A, absence of which causes the progressive accumulation of GM2 gangliosides in the nerve cells of brain thus causing damage to the cells. The accumulation of gangliosides causes deterioration of mental and physical abilities ultimately leading to death by the age of four to five. Being an autosomal recessive disorder, the individual must acquire two Tay–Sachs alleles to

exhibit the disease, i.e., they must be homozygous for it. Tay–Sachs allele is known to be most prevalent in Eastern European people of Jewish descent (Ashkenazi Jews). Although being deleterious in nature, the allele is maintained in the population by its virtue of providing protection to heterozygotes from *Mycobacteria tuberculosis*, the causative agent of infectious disease tuberculosis, thus showing balanced polymorphism. Similarly **cystic fibrosis**, an autosomal recessive disorder most commonly found in Caucasian population, shows balanced polymorphism through heterozygote advantage to the fatal diarrheal disease cholera. It is caused by a mutation in the gene cystic fibrosis transmembrane conductance regulator (*CFTR*) which results in defective chloride channel. Presence of mutation in both copies of the *CFTR* gene in a person causes cystic fibrosis. Cystic fibrosis causes accumulation of mucus in the lungs and gastrointestinal organs thus causing infection and other related defects. Cholera is caused by toxin secreted by the bacterium *Vibrio cholerae* in the small intestine. The toxin acts through intracellular guanine nucleotide binding protein which consequently causes the release of cAMP which in turn induces chloride ion movement through chloride channel into the lumen of the gut. This process causes an osmotic loss of sodium ion and water into the lumen resulting into watery diarrhea (Withrock et al. 2015). In case of *CFTR* heterozygotes where chloride ion channels are less functioning as compared to the normal homozygotes, the influx of ions into the gut lumen is reduced thereby dropping the chance of diarrhea. This selective advantage of CF carriers against cholera allows the maintenance of detrimental CF gene in high frequency by balanced polymorphism. The blood group system in human population also shows balanced polymorphism. The alleles for A, B, AB, and O blood group do not show selective advantage over each other, and genotypic frequencies remain constant from generation to generation for each population.

Apart from human population, balanced polymorphism has also been known to be maintained in animals. **Warfarin resistance** in rats demonstrates one of the best illustrations of balanced

polymorphism (Smith et al. 1993). Warfarin is an anticoagulant which is commercially used as rat poison. It inhibits the production of vitamin K-dependent clotting factor and anticoagulant proteins by disruption of vitamin K synthesis pathway. Warfarin resistance in brown rats (*Rattus norvegicus*) is controlled by an autosomal dominant allele R. However, the resistant individuals also possess a low fitness due to altered vitamin K metabolism. The resistant homozygotes having two R alleles have 20-fold increased demand of vitamin K as compared to heterozygotes (with R and wild-type susceptible S allele), where demand of vitamin K is reduced to as much as two- to fourfold. The resistance allele R exists in balanced polymorphism in the population due to the higher fitness of heterozygotes (RS) over homozygotes (RR) and susceptible (SS). Homozygotes suffer loss of fitness as a result of vitamin K deficiency, whereas susceptibles are affected due to warfarin poisoning. Balanced polymorphism for several genes and inversions is also known to exist in several species of *Drosophila* such as *D. pseudoobscura*, *D. persimilis*, *D. robusta*, *D. ananassae*, etc. due to heterozygote advantage (Singh 2013).

### Evolutionary Significance of Balanced Polymorphism

Balanced polymorphism has known to be one of the important factors in maintaining polymorphism, hence genetic variability in the population. This variability allows an organism to adapt rapidly in the face of changing environmental conditions. In contrast to directional selection where only a particular allele is favored in changing environment, balancing selection maintains the favored allele in an intermediate equilibrium, thus increasing the variability in the genomic region nearby the concerned locus.

Basal Metabolic Rate (BMR)

Karthikeyan Pethusamy<sup>1</sup>, Anshul Gupta<sup>2</sup> and  
Rahul Yadav<sup>3</sup>

<sup>1</sup>Department of Biochemistry, All India Institute  
of Medical Sciences (AIIMS), New Delhi, India

<sup>2</sup>Biochemistry, All India Institute of Medical  
Sciences, New Delhi, India

<sup>3</sup>Indian Institute of Science, Bengaluru, India

Metabolic Rate and Various Types

The total amount of energy used by the animal at a time interval is called its metabolic rate. Basal metabolic rate (BMR) is the rate of energy expenditure by the body during complete physical, mental, and digestive rest (Anthanont et al. 2017). Resting metabolic rate (RMR) is the rate of energy expenditure to perform all vital chemical reactions of the body at rest (McClune et al. 2015).

BMR Versus RMR

BMR differs from the RMR in the fact that BMR is measured under stringent conditions. The RMR is less accurate than the BMR but is used owing to the convenience of measurement. Mitchell defined BMR as the “basal metabolism of an animal is the minimal rate of energy expenditure compatible with life” (Mitchell 1964). The word “basal” in basal metabolic rate refers to the absence of physiological and pathological conditions like exercise, stress, disease, etc.

Standard Metabolic Rate

BMR is applicable only for homeothermic animals that can maintain stable internal body temperature regardless of external influence. Standard metabolic rate (SMR) is used for poikilothermic animals like reptiles and fishes. In

the case of fishes, SMR is the energy demand of all metabolic processes except those associated with swimming, digestion, and catabolism (Benetti et al. 1995).

Conditions to Measure BMR

The BMR measurement should be done in an isolated room ensuring the removal of all psychological and physiological factors that can cause excitement. The subject must be on 12–14 h of caloric fasting and after a night of restful sleep. No strenuous activity must be allowed 1 h before the test and during the test. Thermoneutrality of the subject should be maintained by keeping the temperature of the room between 68 °F and 80 °F.

Conditions Affecting BMR

BMR is affected by both physiological and pathological factors. Lean body mass is the major determinant of BMR. Lean body mass is the weight of a person’s body that is not fat. So, muscular people have more BMR and obese people will have less BMR. Because of relatively more fat, females tend to have less BMR compared to males. Ageing is associated with fatty infiltration of muscle tissues and decreased BMR. Height and weight determine body surface area (BSA). Greater the BSA, greater the heat loss, thus BMR increases. Based on this relation, mammalian basal metabolic rate is proportional to body mass<sup>2/3</sup> (White and Seymour 2003).

BMR increases during growth, reproduction, lactation, and emotionally excited state. Hormones like thyroid hormone, androgens, growth hormone, epinephrine, cortisol also increase BMR.

| ↑ BMR              | ↓ BMR                       |
|--------------------|-----------------------------|
| Fever (pyrexia)    | Protein energy malnutrition |
| Hyperthyroidism    | Hypothyroidism              |
| Cold environment   | Addison’s disease           |
| Cushing’s syndrome | Starvation                  |
| Cachexia           | Obesity                     |
| Exercise           |                             |

## Methods to Measure BMR

Calorimetry (direct and indirect), heart-rate monitoring, and doubly labelled water are the methods used for the calculation of BMR.

Biochemical energy used in the body is released as heat so we can simply measure the heat released by the animal to measure BMR. For this purpose, calorimetry is used. Direct calorimetry involves placing the subject a thermo insulated air chamber. The air temperature within the chamber is maintained at a constant level by forcing the warm air through pipes in a cool water bath. The rate of heat gain by the water bath is measured with an accurate thermometer. This heat gain is equal to the rate at which heat is liberated by the subject's body. Direct calorimetry is practically difficult to perform. So, it is used only for research purposes.

Indirect Calorimetry is based on the concept of “energy equivalent” of oxygen. More than 95% of the energy expenditure of the body is due to reactions of oxygen with the different foods. So, the rate of oxygen utilization gives an accurate measurement of the metabolic rate. One liter of oxygen releases 5.01 calories of energy when metabolized with glucose, 5.06 calories with starch, 4.70 calories with fat, and 4.60 calories with protein. Thus, the quantities of energy liberated per liter of oxygen consumed are nearly equivalent when different types of food are metabolized. For an average diet, the quantity of energy liberated per liter of oxygen used in the body averages about 4.825 calories, which is called the “energy equivalent of oxygen.” By using this energy equivalent, the rate of heat liberation in the body is indirectly calculated.

The heart rate of an animal is directly proportional to its energy expenditure. However, due to physiological variations such as age, sex, body size, and nutritional status, the relationship between heart rate and energy expenditure must be calibrated for each subject measured.

In the doubly labelled water technique, individuals are administered two stable isotopic (nonradioactive) forms of water ( $\text{H}_2^{18}\text{O}$  and  $^2\text{H}_2\text{O}$ ). The rate at which  $^{18}\text{O}$  and  $^2\text{H}$

disappear from the body is monitored for about 7–21 days. Based on the differential rates of disappearance,  $\text{CO}_2$  production is calculated and finally, energy expenditure can be calculated.

BMR is expressed as calories per hour (or per day). The other units of energy like joules and megajoules can also be used.

## BMR in Torpor and Hibernation

Torpor is a physiological state of decreased activity and metabolism seen in many birds and small mammals. Hibernation is the prolonged torpor. In both these instances, the basal metabolic rate of the animal is significantly reduced (Ruf and Geiser 2015).

## Synonyms

DNA; Nitrogenous base

## Definition

A base pair is a unit of the DNA double helix structure.

## Introduction

A very important unit of DNA is the base pair (bp) which is formed between two nucleobases. Nucleobases are nitrogenous biological compounds and form nucleoside which is component of nucleotide. Nucleotides are monomer units of the nucleic acid polymers DNA (deoxyribonucleic acid) and RNA (ribonucleic acid). Nucleotides are composed of three subunit molecules: a nitrogenous base, a five-carbon sugar (ribose or deoxyribose), and a phosphate group; while the nucleosides (such as cytidine, uridine, adenosine, guanosine, thymidine, and inosine) are nucleotides without a phosphate group (Alberts et al. 2002; Zhurkin et al. 2005). The nucleobases are bound to each other by hydrogen bonds to synthesize the building blocks of the

DNA double helix and contribute to the folded structure of both DNA and RNA.

Base pairs through specific hydrogen bonding patterns allow the DNA helix to maintain a regular helical structure that is finally dependent on its nucleotide sequence of pyrimidines and purines. Pyrimidine is an aromatic heterocyclic (six-membered heterocyclics with two nitrogen atoms in the ring) organic compound, nitrogen atoms situated at positions one and three in the ring (Joule and Mills 2012). In nucleic acids, pyrimidine derivative nucleobases are cytosine (C), thymine (T), and uracil (U). While purine (heterocyclic aromatic organic compound) consists of a pyrimidine ring and fused to an imidazole ring. They include the nucleobases adenine (A) and guanine (G). According to Watson-Crick base pairs, a model of DNA structure shows that the molecules (purine and pyrimidine) are cross-linked double-stranded helix where adenine is paired with thymine and cytosine paired with guanine, which projects inward from the deoxyribose sugars and is joined by hydrogen bonds (Zhurkin et al. 2005) (Fig. 1). The nucleotide bases at each position in the DNA double helix are complementary. Complementarity is defined as a relationship between two helices following the lock-and-key principle, and mainly it is the base principle of DNA replication and transcription which have the property to share nucleic acid (DNA/RNA) sequences, when they are aligned antiparallel to each other and termed as complementary. The complementary base pairing allows cells to copy specific information from one generation to another and repair the damage of stored information in the sequences. The structure and data of DNA double helix make DNA well suited for the storage of genetic information. Base pairing also provides the best-suited mechanism for DNA replications using DNA polymerase and transcription by RNA polymerase. These base pairing mechanisms are very specific to recognize the regulatory region of genes. While, in the case of RNA, base pairing occurs within single-stranded nucleic acids, in which guanine-cytosine and adenine-uracil (Watson-Crick base pairs) allow the formation of short double-stranded helices and non-Watson-Crick interactions

**Base Pair, Fig. 1** Chemical structure of base pairing through hydrogen bond in between adenine and thymine (double bond) and guanine base pair with cytosine (triple

bond). The phosphate backbone is situated on the outside and the base pair stands in the middle (D; five-carbon sugar, ribose or deoxyribose)

(e.g., G—U or A—A) allow RNAs to fold (Berg et al. 2002). In between transfer RNA (tRNA) and messenger RNA (mRNA), base pairing creates the foundation for the molecular recognition events that gives result in the nucleotide sequence of mRNA, which are translated into the amino acid sequence of proteins through the genetic code.

Base pairs are the unit to measure the size of an individual gene or an organism's entire genome. Hence, the number of nucleotides in one of the strands is equal to the number of total base pairs. The haploid human genome, i.e., 23 chromosomes, is observed to be about 3.2 billion bases long and to contain 20,000–25,000 different protein-coding genes.

High GC content makes DNA more stable than DNA with low GC content (Yakovchuk et al. 2006). The larger nucleobases like adenine and guanine are the member of double-ringed chemical structures called purines, while the smaller nucleobases (cytosine, thymine, and uracil) are members of single-ringed chemical structures called pyrimidines. The purines and pyrimidines are complementary to each other and effectively

make the pairing. The pairing between pyrimidine-pyrimidine shows unfavorable pairing due to the molecules that are too far to create hydrogen bonding to be established, while purine-purine is very close to pairings so they also show unfavorable pairing and causes overlap repulsion. The proper pairing is found in between purine-pyrimidine base (AT or GC or UA). Base pairing in between GC (purine-pyrimidine) content shows higher melting temperatures, therefore, the genomes of extremophile organisms such as *Thermus thermophilus* are particularly GC-rich (Lorenz et al. 2017).

## Base Analogs and Intercalators

Some chemical analogs of nucleotides can replace the place of appropriate nucleotides and begin a noncanonical base pairing, leading to mutations. One common mutagenic base is 5-bromouracil, which resembles thymine (T) but can base pair to the guanine (G) in its enol form. On the other hand, some analogs of bases are intercalators ethidium bromide and acridine which cause frameshift mutations. The bp (base pairs), kbp

(kilo base pairs), Mb (mega base pairs), and Gb (giga base pairs) are commonly used to describe the length of a DNA/RNA molecule.

## Role of Base Pair in Animal Cognition and Behavior

The four base pairs of DNA cause variations in the living world due to the variations in the sequences of DNA by their interactions with the environment. The genetic diversity of a species exists at three levels (I) heterozygosity (genetic diversity within individuals), (II) genetic diversity between individuals within a population, and (III) genetic variations between populations (Mandal 2015). Genetic diversity is the heritable variation within a population and between populations. Genes and chromosomal mutations also cause the genetic variations. Mostly genetic variation due to base pairs over a single generation occurs through shuffling of the homologous chromosome, fusion of gametes during sexual reproduction, and cross-over. All the variations depend upon environmental conditions whether such changes (structural and functional) are beneficial or harmful or neutral in the present as well as for the future.

Evolutionary responses of previous populations are allowed by genes for selection of behavior. The genetic characters are mainly resolute by genes which play role in many behaviors, a change in single protein brings distinct phenotype. Expression of genes is mainly influenced by the external environmental factors via nervous and hormonal mechanisms. Synthesis of one polypeptide is governed by the gene, which is the functional unit of the genome. In a gene, cistron is the functional unit and contains over a hundred points where the mutation can take place, which causes the detectable phenotypic effect (Lehninger 2000). Cistron is responsible for coding of the polypeptide chain of an enzyme. The genes carry specific codes for amino acid which can synthesize protein. Monomorphic loci (section on the chromosome) contain the single most common segment of code which is 95–99% similar to each individual. Evolutionary responses of previous populations are allowed by genes for selection of behavior (Davis and Shaw

2001). The genetic characters are mainly resolute by genes which play role in many behaviors, a change in single protein brings distinct phenotype. Expression of genes is mainly influenced by the external environmental factors via nervous and hormonal mechanisms (Booij et al. 2015).

## Summary

The genetic information is carried in the linear sequence of nucleotides in DNA. Each molecule of DNA is held together by hydrogen bonds between G—C and A—T base pairs and forms two complementary strands of nucleotides. The copy of the genetic information occurs by the use of one DNA strand as a template for the formation of a complementary strand. DNA stores all genetic information for all the proteins that organism will ever synthesize.

## Base-Rate Neglect

Thomas R. Zentall  
University of Kentucky, Lexington, KY, USA

## Synonyms

[Biased decision making](#)

## Introduction

Base-rate neglect is a phenomenon in which under certain conditions, humans are known to reliably overestimate the probabilities of events, even though there is sufficient information provided to arrive at the correct probability (Kahneman and Tversky 1972). In a common version of the problem, originally proposed by Tversky and Kahneman (1980), participants are told that patients presenting with a particular set of symptoms have a 10% chance of having contracted a particular disease. Furthermore, they are told that there exists a diagnostic test, the accuracy of which is 80% (in detecting the disease when it is present and in correctly indicating that the disease is absent when it is not present). Participants are then asked, “Given that the symptoms are present, and the test results are positive, what is the probability that the patient has the disease?” Most participants guess that it is very likely (between 60% and 80%) that the patient has the disease.

In making this judgment, the participants fail to consider sufficiently the fact that the disease is relatively rare (i.e., they tend to underestimate the effect of the base rate on the probability). In fact, the conditional probability of correctly identifying the presence of the disease is equal to the probability that the disease is present, times the probability that the test is correct, which is  $0.10 \times 0.80 = 0.08$ , whereas the probability of incorrectly identifying the disease when it actually was absent is equal to the probability that the disease is absent times the probability that the test is incorrect, which is  $0.90 \times 0.20 = 0.18$ . This means that the probability of being correct given a positive test is only  $0.08/(0.08 \times 0.18) = 0.31$ , or less than one chance in three. Thus, humans generally overestimate the likelihood that the disease is present because they underestimate the base rate. Similarly, the relative neglect of base-rate is responsible for the exaggerated fear that people have of air travel, of walking the streets of New York City, or of their children being shot at school.

## Base-Rate Neglect in Pigeons

Are other animals subject to the same kind of errors? To answer this question, one needs to examine the performance of animals on a task in which base-rates may play a role. In a conditional discrimination (e.g., matching to sample), an initial or sample stimulus indicates which one of the two (or more) test or comparison stimuli is correct (Skinner 1950). According to Hartl and Fantino (1996), in such a task, comparison choice for pigeons should depend on two factors: (1) if the sample can be remembered, the conditional probability of each comparison being correct, given presentation of one of the samples and (2) if the sample cannot be remembered, the relative probabilities of reinforcement associated with the comparisons.

Typically, the two samples are presented with equal probability and the relative probabilities of reinforcement associated with the comparisons are the same. If those probabilities are not the same, however, and one introduces a delay

between the offset of the sample and the onset of the comparison stimuli, one might expect to see a bias in comparison choice (see Goodie and Fantino 1995, 1996 for evidence of such an effect with humans).

Alternatively, one could introduce a second matching task that involves two new comparison stimuli and one new sample, but the second task shares the other sample with the first matching task (see Fig. 1; Zentall and Clement 2002). Thus, there would be three rather than four samples, and the frequency of presentation of one sample would be twice that of each of the other two. Given the presentation of a pair of comparison stimuli, however, the probability that it had been preceded by one of the two possible samples would be equal.

Thus, if each of the four trial types appeared equally often, each of the comparison stimuli would be associated with reinforcement on 25% of the reinforced trials. However, the same would not be true of the samples. Two of the samples would each be presented on 25% of the trials, whereas the third would be presented on 50% of the trials.

**Base-Rate Neglect, Fig. 1** Design of Zentall and Clement (2002). Pigeons were trained to choose the red comparisons when the sample was red and the green comparison when the sample was green. They were also trained to choose the vertical comparison when the sample was red and the horizontal comparison when the sample was white

The question is, if a delay is introduced between the offset of the sample and the onset of the comparison stimuli, assuming that there is forgetting of the sample, would the pigeons use the probability of reinforcement associated with the comparison stimuli (the base-rate) to determine choice or would the pigeons be influenced by the sample probabilities (neglect the base-rate). One of the samples appeared twice as often as the other but half of those occurred with the other pair of comparison stimuli. Zentall and Clement (2002) found a strong bias to choose the comparison associated with the more frequently occurring sample, even though that sample had not occurred more frequently with either comparison stimulus. These pigeons neglected the base-rate.

Another approach to base-rate neglect was used by DiGian and Zentall (2007). In that study, the bias was induced by presenting one sample on 80% of the trials, but correct choice of the associated comparison was reinforced only 25% of the time (see Fig. 2). The other sample was presented only 20% of the time, but correct choice of the associated comparison was always reinforced. With this design, in the absence of memory for the sample, choice of either comparison stimulus was reinforced 10% of the time (the base rate). Nonetheless, with increasing delay between the offset of the sample and the onset of the comparison stimuli, the pigeons showed a strong preference for the comparison associated with the more frequently presented stimulus. Once again, the pigeons were influenced by the irrelevancy of the sample frequency.

A third approach to the question of base-rate neglect was developed by Zentall et al. (2008). They also used three samples, but only two comparison stimuli (see Fig. 3). On 1/3 of the trials, the sample was green and correct choice of the green comparison was reinforced 100% of the time. On 1/3 of the trials, the sample was red and correct choice of the red comparison was reinforced only 50% of the time. On the remaining 1/3 of the trials, the sample was yellow and correct choice of the red comparison was reinforced 50% of the time. Thus, the green comparison was correct on 1/3 of the trials, whereas the red comparison stimulus was correct on 2/3 of the trials, but

B

**Base-Rate Neglect, Fig. 2** Design of DiGian and Zentall (2007). Pigeons were trained to choose the red comparisons when the sample was red and the green comparison when the sample was green. Red sample appeared 80% of

the time but correct red comparison responses were reinforced only 25% of the time. Green samples appeared 20% of the time and correct green comparison responses were reinforced 100% of the time

**Base-Rate Neglect, Fig. 3** Design of Zentall et al. (2008). Red, green, and yellow samples were presented equally often. Correct green comparison responses were

always reinforced. Correct red comparison responses were reinforced 50% of the time, whether the sample was red or yellow

correct choice of it was reinforced only 50% of the time. With this design, in the absence of memory for the sample, choice of either comparison stimulus was reinforced 1/3 of the time (the base rate). Once again, because samples associated with red comparison occurred on 2/3 of the trials, the pigeons were biased to choose the red comparison. They did so, in spite of the fact that, in the absence of memory for the sample, the probability of reinforcement for choice of either comparison was the same (1/3).

are two sample, correct-comparison response chains. If that was all that they learn, then in the absence of memory for the sample there should be no comparison response bias.

## Conclusions

The results of these experiments demonstrate that pigeons show an effect of base-rate neglect similar to that of humans. The results are also inconsistent with Skinner's (1950) claim that when animals learn a conditional discrimination all they learn

## Basic Rank

Andreas Koenig  
Department of Anthropology, Stony Brook  
University SUNY, Stony Brook, NY, USA

## Synonyms

[Dominance rank](#); [Rank](#); [Status](#)

## Definition

The relative position of an individual within a group or within a population only affected by physiological or morphological characteristics or both.

## Introduction

In many animals, individuals compete over access to limited resources such as food, water, mating partners, space, and so on. This competition can

take the form of physical combat, mere displacements, or displays; or it may be decided by one individual retreating spontaneously without preceding interactions (interactions obvious for a human observer; Dugatkin 2014). Competition occurs between individuals of the same group, between groups of individuals, or between solitary individuals. If individuals (or groups) are able to recognize each other and interact repeatedly, the outcome of their interactions, i.e., winning or losing, can be more or less stable so that the relative position of an individual (or a group) can be predicted with high certainty. In this situation, an individual or a group can be assigned a status or dominance rank (or rank, for short) relative to another individual or another group; one individual (one group) is said to be higher or lower ranking than another (Clutton-Brock 2016).

On the most basic level, the outcome of competitive interactions is related to the morphological or physiological characteristics of an individual; a condition known as “basic rank” (Kawai 1965). Despite the fact that groups can compete against other groups and a rank can be assigned, the concept of basic rank has only been applied to individuals. Importantly, beyond the effects of morphology and physiology, additional factors can influence the outcome of a competitive interaction and, hence, the relationship between two individuals. The resulting system is coined “dependent rank” (Kawai 1965). Originally, Masao Kawai (1965) found that the presence of kin changed the rank relationship between individuals in Japanese macaques. Today, such effects are known for several primate species, spotted hyenas, and jackdaws (Clutton-Brock 2016). We also know a multitude of other influences on rank such as winner-loser effects, bystander effects, audience effects, and so on (Dugatkin 2014). Still, the basic rank of an individual relative to others is the underlying characteristic of competitive relationships within groups and populations.

## Individual Characteristics and Rank

In the simplest case, the outcome of a competitive interaction between two individuals can be

characterized based on three variables: (i) the value of the resource that is contested, (ii) the potential costs of the contest, and (iii) the probability of winning (or losing) (Maynard Smith and Parker 1976; Dunbar 1988). If we assume for simplicity that the value of a resource is similar for both contestants (which is usually not the case in reality; imagine a satiated and a starving individual vying for the same food item), we can model the way in which the costs and the probability of winning will vary (Enquist and Leimar 1983). In such a case, we can safely assume (see examples below) that those fighting abilities will determine the outcome that are related to body size, strength, or weaponry such as canine size, size of antlers, etc. An individual facing an opponent with particularly large canines has a high risk of injury. A bigger or stronger animal has a higher chance of winning. These aspects immediately explain why younger and smaller individuals often occupy lower ranks than older and larger individuals (a situation resulting in “age-graded” ranks). However, even adult individuals vary in size, strength, and weaponry, such that the ranks of two individuals or the rank order within an entire group correlates with fighting abilities (Kappeler 2006). Pinnipeds and ungulates provide good examples both for females and for males, although the connection with age, body size, and weaponry is not always consistent (Clutton-Brock 2016).

In addition to morphology, physiology can also play a crucial role. Winning a physical combat can be decided by the aggressiveness of an individual, which in turn is often a function of the hormonal status such as the level of androgens (Wingfield et al. 1990). Again, this may relate directly to the age and developmental status of males, because androgen levels increase during ontogeny. However, even among adult males, androgen levels differ. Particularly during periods of instability, dominant males may be characterized by higher levels of testosterone, higher aggressiveness, and lower stress levels (lower corticosteroid levels) than lower ranking males (Sapolsky 1993). As with fighting abilities, the relationship between physiological variables and male rank is not always consistent but varies across populations

and species (Clutton-Brock 2016). In a few species, such as in spotted hyenas, a tight relationship between androgens and rank has been described for females. Notably, here a female’s rank and hormonal status during pregnancy has consequences for the aggressiveness of her cubs. Cubs, both females and males, of high-ranking mothers are exposed to high levels of androgens during fetal development and express high levels of aggression later on (Dloniak et al. 2006). Thus, basic rank does not only relate to competitive interactions and rank of a female but can have downstream effects on her offspring.

## Conclusion

Basic rank refers to the dominance rank of an individual purely based on individual characteristics such as hormonal status, maturity, and more generally size, strength, and weaponry. It is important to note that the basic rank of an individual is often affected by additional variables such as the actual status of an individual (e.g., hunger level which affects the value of a resource) and the social environment through kinship, winner-loser effects, bystander effects, audience effects, and the like.

## Introduction

In 1948, the English geneticist Angus John Bateman published a pioneering study of genetic parentage in

the fruit fly *Drosophila melanogaster* (Bateman 1948). Bateman set up small breeding populations of flies and used visible mutations to determine the mother and father of the resulting offspring. He then used these data to address the question of why competition for mates is usually stronger in males than in females. Although some authors have criticized empirical details of Bateman’s study (e.g., Snyder and Gowaty 2007), his conceptual framework has profoundly influenced modern sexual selection theory.

When males and females occur in roughly equal numbers – as they do in *D. melanogaster* – the average number of offspring produced by members of each sex must also be equal, because each offspring has exactly one mother and one father. Bateman showed, however, that the variance in offspring number was higher in males than females. He attributed this result to two main causes: (1) males were more variable than females in the number of matings they achieved, and (2) the correlation between offspring number and the number of mates was stronger in males than in females. This stronger relationship, Bateman argued, arises from the fundamental sex difference in gamete size. Because sperm are smaller and more numerous than eggs, female offspring production is less strongly limited by fertilization opportunities. Males should consequently experience stronger selection to increase their number of mates, at least in species where their only contribution to the next generation is their sperm.

Bateman’s ideas lay largely dormant until the renaissance of sexual selection theory in the 1970s, where they were revived in particular by Trivers (1972). Bateman’s observations and conclusions were integrated with formal selection theory (Arnold and Duvall 1994; Jones 2009; Henshaw et al. 2018), which led to more precise quantitative definitions of Bateman’s principles. Perhaps the most important insight was that the strength of sexual selection is related to the slope of the relationship between reproductive success (number of offspring) and mating success (number of mates). Arnold and Duvall (1994) showed that this relationship could be quantified using a regression coefficient (Fig. 1), and they named this quantity the *sexual selection gradient*.

**Bateman Gradient, Fig. 1** Hypothetical relationships between an individual's number of mates  $M$  and their number of offspring  $R$ , assuming that (a) additional mates after the first are detrimental to average offspring production, or (b) average offspring production increases linearly with the number of mates. Small blue circles represent individual mate and offspring numbers; large green circles

represent the average offspring number of individuals with any given number of mates (i.e., the Bateman function); the purple line represents the simple linear regression of offspring number on mate number. The Bateman gradient  $\beta_{ss}$  is the slope of this regression line. Offspring number has been standardized to have a mean value of one

Andersson and Iwasa (1996) later suggested the name *Bateman gradient* to distinguish it from other types of selection gradients.

## Definition

The Bateman gradient  $\beta_{ss}$  quantifies the slope of the relationship between an individual's number of mates or matings (i.e., their mating success  $M$ ) and their number of offspring (i.e., their reproductive success  $R$ ). Most commonly, Bateman gradients are calculated as the slope of a simple linear regression of reproductive success on mating success (Arnold and Duvall 1994; Jones 2009; Henshaw et al. 2018; Fig. 1). Explicitly, this means that:

$$\beta_{ss} = \frac{\text{cov}(M, R)}{\text{var}(M)}$$

Bateman gradients are estimated separately for each sex, usually over a constrained time period such as a breeding season. They are best

calculated using *relative* reproductive success, which is standardized by dividing each individual's reproductive success by the mean reproductive success of all individuals of the same sex (Jones 2009). In this case, the Bateman gradient can be interpreted as a linear selection gradient on mating success (Arnold and Duvall 1994). Some authors additionally recommend mean-standardizing mating success (Jones 2009).

## Measurement and Interpretation

Three issues should be kept in mind when measuring and interpreting Bateman gradients. First, the most intuitive interpretation of a Bateman gradient is causal – how much would a typical individual's reproductive success increase if they were granted an extra mating? Despite this intuition, Bateman gradients are most often measured in freely mating populations, where mating and reproductive success covary naturally (Anthes et al. 2017). Such correlative studies are vulnerable to confounding factors that affect both

mating and reproductive success, which complicates interpretations of the Bateman gradient. If potential confounders are identified and measured, then they can be included as covariates in the regression of reproductive success on mating success. The Bateman gradient can then be defined as a partial regression coefficient (Henshaw et al. 2018). Nonetheless, the potential for unmeasured confounders means that manipulative experiments are essential to pin down the causal relationship between mating and reproductive success (Anthes et al. 2017).

Second, Bateman gradients condense the relationship between mating and reproductive success into a single number (the “slope”). However, such relationships are often not straight lines; rather, their steepness may vary with the number of matings. More generally, a *Bateman function* represents the average reproductive success of individuals with each integer number of matings (Fig. 1). For individuals with zero mating success, reproductive success is necessarily also zero, as no offspring can be conceived without mating. After the first mating, reproductive success may continue to increase, remain flat, or even decrease (e.g., if mating itself is dangerous or harmful), depending on a species’ ecology and mating system (Anthes et al. 2017). Despite these nuances, the interpretation of Bateman gradients as selection gradients on mating success always holds, regardless of whether the Bateman function is linear or nonlinear.

Third, Bateman gradients are highly sensitive to technical issues affecting estimates of mating and reproductive success. In many studies, matings are not observed directly, but rather inferred by reconstructing the parentage of offspring. Only matings that lead to offspring are counted towards an individual’s “mating success,” which can lead to a spurious strengthening of the estimated relationship between mating and reproductive success. Unsurprisingly, Bateman gradients based on genetic information alone are almost always higher than those based on observations of mating interactions (Anthes et al. 2017). Another issue is that when individuals are sampled from natural, open populations, mating and reproductive success are inevitably sampled incompletely for some individuals. This can lead to biased estimates of Bateman gradients. Statistical approaches exist to

ameliorate such bias as long as certain assumptions are met (Jones 2015).

## The Strength of Sexual Selection

Sexual selection can be conceptualized as a type of natural selection that acts via causal pathways involving mating or fertilization success (Henshaw et al. 2018). Selection via mating success in particular is sometimes termed *pre-mating sexual selection* (Fig. 2). Using a path-analytic framework, the strength of pre-mating sexual selection acting on a trait can be decomposed into two components, with one component representing the association between the trait and mating success and the other representing the association between mating and reproductive success (Arnold and Duvall 1994; Jones 2009; Henshaw et al. 2018). One such decomposition is:

$$x = \beta_{ss}m$$

Here  $x$  is the strength of sexual selection,  $\beta_{ss}$  is the Bateman gradient (calculated as a simple or partial regression coefficient), and  $m$  is the covariance between the trait and mating success (known as the *mating differential*). For traits that are standardized to have a variance of one, the strength of pre-mating sexual selection  $x$  is limited in magnitude by:

**Bateman Gradient, Fig. 2** Pre-mating sexual selection is any selection acting via causal pathways involving mating success  $M$  (shown in red). Pre-mating sexual selection on an arbitrary trait  $Z$  can be decomposed into two components: the mating differential  $m$ , which represents the relationship between the trait and mating success, and the Bateman gradient  $\beta_{ss}$ , which quantifies the relationship between mating success and reproductive success  $R$ . The variable  $r$  represents any remaining selection acting on  $Z$ , other than pre-mating sexual selection

$$|x| \leq |\beta_{ss}| \sqrt{\text{var } M}$$

This upper bound, known as the *Jones index*, is informative even for traits that are not included in the analysis (Jones 2009; Henshaw et al. 2018). It is unbiased only if the estimate of  $\beta_{ss}$  controls for all factors that confound the relationship between mating and reproductive success. The Jones index was highly correlated with the strength of pre-mating sexual selection in a simulation study (Henshaw et al. 2016).

## Sex Differences in the Bateman Gradient

In most animal species, males contribute only their sperm to the next generation. In such cases, Bateman gradients are invariably larger for males than for females (Janicke et al. 2016). However, large female Bateman gradients may occur for at least two reasons. First, if mate encounters are rare, then both males and females may often be mate-limited. Second, if males contribute substantial resources towards raising offspring, or provide nuptial gifts to their partners while mating, then female reproductive success may increase steeply with the number of mating partners (Trivers 1972). In rare cases, including several species in the pipefish family, paternal investment in offspring has led to female Bateman gradients exceeding their male counterparts (Janicke et al. 2016).

## Batesian Mimicry

Fadia Sara Ceccarelli

Department of Conservation Biology, Centro de Investigación Científica y de Educación Superior de Ensenada, Ensenada, BC, Mexico

## Definition

Mimicry – or the phenomenon of one organism (the mimic) displaying characteristics of an unrelated organism (the model) – is divided into different categories, depending on the function or outcome of the imitation. In the case of **Batesian**

**mimicry**, the acquired resembling characteristics offer a protective function to the mimic, in that the chances of the organism being eaten by potential predators are reduced. Batesian mimicry therefore involves three parties: the model, the mimic (also known as the signaler), and the predator (also known as the signal receiver or the operator), all of which belong to different species found in the same geographical area (but not necessarily in strict sympatry).

## Background

Batesian mimicry is named after the nineteenth century British naturalist, Henry Walter Bates, in honor of his work with Amazonian butterflies (Bates 1862). Bates documented dozens of butterfly species belonging to the families Ithomiinae and Heliconinae, noticing that several unrelated species living in the same areas showed strikingly similar appearances. His explanation for this phenomenon was that some of these species must be unpalatable or noxious to predators such as birds, so other butterflies evolved similar colors and patterns, “deceiving” the predators and so avoided being preyed on. These observations and explanations came in a timely manner with the newly emerging theory of natural selection, providing one of the strongest arguments for predator-mediated selection. In fact, both Charles Darwin and Alfred Russel Wallace were greatly inspired by Bates’ work, Darwin mentioning it several times in his most famous publication, *The Origin of Species*.

## Conditions of Batesian Mimicry

The conditions that shape Batesian mimicry, and by which it is upheld, involve (1) the noxiousness, distastefulness, or general unpalatability of the model; (2) the accuracy of the mimic in imitating the model; and (3) a capacity for learning to avoid the noxious models (and hence the mimics too) by the predator (Rettenmeyer 1970; Mappes and Alatalo 1997). Expanding on the first point, the effectiveness of the mimicry therefore depends on

factors such as the noxiousness or unpalatability of the model. Generally, this translates as a distastefulness or toxicity for the predator brought about by certain chemical compounds known as allomones, which in insects, for example, are divided into Class I chemicals such as alkaloids and cyanides which poison, irritate, or injure predators; and Class II chemicals such as aldehydes and aromatic ketones, which deter predators through adverse smells, but are essentially harmless. On the other hand, a potential prey item can also become unpalatable if it has developed physical defense mechanisms such as spines, stings, and/or aggressive-defensive behavior.

The next point regarding the conditions for Batesian mimicry involves the mimic’s accuracy in imitating the model, which may at times be a more subjective matter. In other words, the human perception of a mimetic form may differ from the predator’s making a seemingly “imperfect” mimic in fact effective to the predator’s sensory system. Nevertheless, numerous studies have addressed the issue of the variation in mimetic forms, whereby some mimics appear to imitate their models almost perfectly, whereas others show less of a resemblance, earning the title of “poor” or “imperfect” mimics (Edmunds 2000). Explanations for the existence of these “imperfect” mimics, apart from observer subjectivity, include the possibility of the mimic imitating more than one model, thus having a general rather than one-species-specific form. Alternatively, the selection pressure to closely resemble the model may not be very strong if, for example, the model is highly toxic and an approximate resemblance suffices for protection from predation. An “imperfect” mimic may also simply be in the process of converging toward the model’s phenotype (i.e., the expressed character). Finally, while selection would favor a more model-specific phenotype, there are trade-offs involved, including the loss of polymorphism (from the Greek meaning “many forms”), an evolutionarily advantageous condition for populations (Lindström et al. 1997; Joron and Mallet 1998; Sherratt 2002; Penney et al. 2012).

The final point relates to the theory that for Batesian mimicry to be effective, the mimics should not outnumber the models, otherwise

predator learning will be compromised. This ties in with the theory of frequency-dependent selection, where the higher the proportion of models to mimics, the more likely the predator is to learn to avoid the prey (Pfennig et al. 2001). Conversely, if there is a relatively high density of mimics, the predators may only ever encounter the harmless mimic, not learning to avoid that particular phenotype. Predator learning is not essential in all cases of Batesian mimicry, as predator avoidance toward certain stimuli can also be innate. Nevertheless, many cases of Batesian mimicry exist where a “naive” predator must first suffer an adverse reaction from consuming harmful prey, before learning to avoid organisms displaying a specific characteristic related to the harmful prey. In many cases, this characteristic involves bright colors and patterns presumed to be “warning signals” advertising the potential prey’s noxiousness to predators, a phenomenon known as aposematic coloration or aposematism. An example of aposematism in insects is the yellow-and-black striped abdomens of bees and wasps, signaling the presence of their stings and venom. The hoverflies, a group of harmless insects, have acquired the yellow-and-black striped abdomen characteristic, thus turning them into Batesian mimics, not of any species in particular, but of the whole aposematically protected group of bees and wasps. So Batesian mimics can rely on the resemblance of a general characteristic, or they can mimic specific model species, at times very accurately.

## Visual Batesian Mimicry

When talking about Batesian mimicry, the predator’s sensory channel targeted by the mimic must be specified. Most recorded cases are of visual Batesian mimicry, relying on the predator’s sense of sight to exert the resemblance. Visual Batesian mimicry can be found from model-mimic systems of species belonging to the same family, through to taxonomically distant groups even from different phyla, keeping in mind that greater resemblance is more easily achieved in evolutionary terms between closely related

models and mimics. The systems which sparked W.H. Bates’ interest and brought forth his developing the theory were in fact between butterfly species mostly belonging to the same – or closely related – families, as mentioned earlier. Another example of a model-mimic system in which both parties belong to the same family is the Batesian mimicry by several tenebrionid beetle species of a particular genus, *Eleodes* (Tenebrionidae), which deter predators by producing noxious chemicals (Smith et al. 2015). In vertebrates, a thoroughly studied example of Batesian mimicry between closely related groups relying on aposematic coloration is the mimicry complex between several species of the highly venomous coral snakes (six genera of the family Elapidae) and their Batesian mimics which include the scarlet snakes (family Colubridae) *Cemophora coccinea* and *Lampropeltis elapsoides*. In other vertebrate groups, examples of Batesian mimicry include the harmless cardinalfish *Fowleria* sp. (family Apogonidae) resembling the venomous Scorpionfish *Scorpaenodes guamensis* (family Scorpaenidae) (Seigel and Adamson 1983), the red morph of the red-backed salamander *Plethodon cinereus* (family Plethodontidae) mimicking the highly toxic Eastern newt *Notophthalmus viridescens* (family Salamandridae) (Brodie and Brodie 1980), or in mammals perhaps the resemblance of the insectivorous aardwolf to the striped hyenas in their fur pattern.

Within the phylum Arthropoda, due to their extreme diversity, an immense number of cases of Batesian mimicry can be found between members of different orders and classes, especially the insects (Rettenmeyer 1970). Within the insects, the ants are an outstanding group of models for Batesian mimicry, due to one – or a combination – of the following characteristics: colonies with high numbers of individuals, aggressive nature, hard cuticles in some cases with spines, bites, stings, and the presence of formic acid in some families. It therefore comes as no surprise that ant mimicry, in particular myrmecomorphy (the morphological resemblance to ants), has evolved at least 70 times in arthropods, with more than 2000 described species, belonging to over 200 genera in

54 families from groups such as the plant bugs, staphylinid beetles, and spiders (McIver and Stonedahl 1993). Ant-mimicking spiders can be found in at least 13 families, with the jumping spiders (family Salticidae) containing the highest number of myrmechomorphic genera and species (Cushing 2012).

Some salticid genera's species are exclusively Batesian mimics of ants. An example is the genus *Myrmarachne*, which contains around 200 described, globally distributed species, which resemble ants in general body shape, coloration, and texture. The high species diversity of this genus backs up the numerous strategies within the Batesian ant mimicry, which have evolved in different *Myrmarachne* species. For example, many species display what is known as transformational mimicry, whereby a different ant species serves as a model at each of the spiders' instars (the phase between two molts during their growth), keeping the relative sizes of the model and the mimic similar (Edmunds 1978). The protective benefits of Batesian mimicry are further enhanced by species such as *Myrmarachne melanotarsa*, which – unlike most spiders which are solitary – aggregate into groups, thus resembling ants in colonies even more, in a strategy termed collective mimicry (Nelson and Jackson 2009). Many species of the genus also display sexual dimorphism, meaning that males and females are different in some way. In the case of *Myrmarachne*, the males have enlarged chelicerae (or fangs), a character thought to be sexually selected. Although this might appear to reduce the males' resemblance to ants, in fact the enlarged chelicerae are probably a case of compound Batesian mimicry, where the spider looks like an ant carrying something (usually dead ants) in their mandibles (Nelson and Jackson 2006). As mentioned before, polymorphism is widespread among natural populations. Hence, many species of ant-mimicking spiders are also polymorphic, mainly in coloration and patterns. In some cases, the polymorphism fits in with individual mimics from the same species resembling different model ant species (Ceccarelli and Crozier 2007), which in turn may favor the overall dynamics of frequency-dependent predator-mediated selection.

Finally, Batesian mimicry can even be found in model-mimic systems between distantly related species belonging to different phyla. Such is the case, for example, in the chordate-arthropod model-mimic example where the hawk moth caterpillar (*Hemeroplanes triptolemus*, family Sphingidae) extends its segments to resemble a snake and thus ward off potential predators (Hossie and Sherratt 2013).

## Behavioral Batesian Mimicry

In some cases of Batesian mimicry, the visual resemblance of the mimic to the model is enhanced by the mimic's behavior. Although this is strictly speaking visual mimicry as well, it deserves a special mention, since it is not only the morphology which has adapted, but also some behavioral traits, usually the way in which the model moves. In the examples given above, behavioral mimicry can be observed in the hawk moth, which does not only have a fake “snake's head,” but also moves the fake head from side to side, as a snake does. A special case of behavioral mimicry can also be observed in many ant-mimicking spiders. Since spiders have four pairs of legs and no antennae, while ants have three pairs of legs and a pair of antennae, to increase the resemblance to ants, several Batesian ant-mimic spiders lift their first pair of legs and wave them around as ants wave their antennae. This behavioral mimicry carried out by many spiders is known as “antennal illusion” and is in some cases further reinforced by special colorations of the spiders' first pair of legs (Ceccarelli 2008).

## Acoustic Batesian Mimicry

Visual Batesian mimicry is, as mentioned before, by far the strategy with the most cases recorded, emerging from ecological interactions where the predators hunt by using visual cues. However, many predators (especially nocturnal ones) also use their sense of hearing (and smell) to find prey, so there are also documented cases of acoustic

Batesian mimicry, where the mimic imitates a model's sound to deter potential predators. One example of such a system is the imitation by other moths of the noxious tiger moth's ultrasonic warning sounds in response to bats echolocation. The red bats (*Lasiurus borealis*), for example, learn to avoid the tiger moths (*Cynia tenera*) by associating the moth's warning sounds to the noxious prey, so when the palatable moth species produce similar ultrasonic sounds they will not be preyed on by the bats (Barber and Conner 2007). Another example of acoustic mimicry is found in the burrowing owl (*Athene cunicularia*), which produces a hissing sound like the warning of rattlesnakes (*Crotalus* spp) (Rowe et al. 1986). In this case, the potential predator may span a wide range of organisms which are deterred by the sound of a rattlesnake, thus avoiding the burrowing owl. The asp viper (*Vipera aspis*) is another venomous snake which serves as a model for Batesian mimicry by the harmless viperine snake (*Natrix maura*), visually as well as acoustically through the resemblance of the hissing sound produced by the two snakes (Aubret and Mangin 2014).

## Batesian Mimicry Evolution

It is clear that the study of acoustic Batesian mimicry lags behind the multitude of studies on visual mimetic systems. In any case, Batesian mimicry in general is a topic of great interest to biologists and continues being an ever-expanding field. In particular, with the advancement of molecular-based studies, the evolution of mimicry can be investigated at a genetic level. While a theory (Charlesworth and Charlesworth 1975), backed up by a genomic study in butterflies (Joron et al. 2011), has been put forward stating that mimicry is likely to be based on supergene complexes, much work remains to be done on an empirical basis. Similarly, more empirical studies backing up the various mathematical models of the evolution of mimicry are required (Nur 1970; Matessi and Cori 1972; Holmgren and Enquist 1999). The evolutionary dynamics of Batesian mimicry are very varied depending on the nature of the species involved, ranging from

one-sided advergence (Brower and Brower 1972) or even adaptive radiation of the mimic with no effect on the model (Ceccarelli and Crozier 2007), through to coevolution type scenarios where the presence of the mimic has an effect on the fitness of the model, thus influencing its evolution (Turner 1995).

## Introduction

Studies related to bear (*Ursidae*) cognition emerged relatively recently in scientific history compared to other mammalian groups (e.g., rodents, primates), and have focused strongly on establishing the cognitive capabilities of this taxa and the evolutionary mechanisms responsible for driving their cognition. The relative sociality of a species has been suggested to be linked to the evolution of key cognitive capabilities such as concept formation, language, and complex problem solving (Sewall 2015). This a critical area of research, as the Ursids are relatively solitary in nature compared to other caniform carnivores (e.g., domestic dogs, wolves). However, bears exhibit delayed ontogeny, remaining with their mothers for a period of up to 3–5 years, depending on the species and habitat, which allows for vertical transmission of skills (social learning from mother to offspring). Additionally, many species continue to stay with their siblings after leaving their mothers, allowing for horizontal transmission of skills (social learning from sibling to sibling, Gilbert 1999). Some, however, argue that it is not necessarily sociality of a species, but larger relative brain size to body size that is related to greater cognitive sophistication (Benson-Amram et al. 2016). Bears are known to have one of the largest brain-to-body-size ratios of terrestrial mammalian carnivores (Benson-Amram et al. 2016). Still others look to ecological factors that may have played a role in the evolution of these capabilities. Specifically, hunting/foraging strategies and diet are of particular interest to researchers (Gilbert 1999). Evidence gained from studying bears, could help clarify the mechanisms at play in driving cognitive evolution.

Bear cognition has been studied from a basic research approach as well as from an applied, animal welfare perspective. The knowledge gained from basic research aimed at understanding what cognitive abilities bears possess and why/how these abilities may have evolved hope to inform animal welfare policies both within animal facilities that house bears, but also conservation efforts and improved human-wildlife interactions in the wild. In addition, less formal research done by caretakers in animal facilities

offer unique insight into capacities not fully understood in strictly controlled experimental settings.

## Basic Research on Bear Cognition

**Concept Formation** The ability to organize stimuli in the environment into concepts has been well documented in a wide variety of non-human species. Concepts are mental representations of information formed during the process of categorization. Increased experience corresponds to an increased cognitive complexity, enabling the comprehension of complex concepts as well as linkages between these concepts. The links within and between concepts allow for painting a broader picture of the perceptual and social world.

**Natural Concept Formation at Varying Levels of Abstraction** Little research on bear cognition occurred after Gordon Burghardt's pioneering work in the 1970s and 80s (e.g., Bacon and Burghardt 1976, 1983), but there has been a lot of recent interest in the area of bears' ability to form concepts for natural categories at what is referred to as, different levels of abstraction. Essentially, natural categories build on themselves from least to most inclusive and from least to most abstract. This ability is essential for survival in the wild – for example, for the distinction between venomous and non-venomous snake species (Rogers et al. 2014).

Using a computerized touch screen task previously used to test the same skills in great apes (gorillas, orangutans, and chimpanzees), Vonk et al. (2012) tested three captive American black bears' (*Ursus americanus*) ability to form concepts at five levels of abstraction: concrete – black bears (S+) versus humans, concrete/intermediate – polar bears (S+) versus mixed bears, intermediate – primate (S+ for two bears) versus hoofstock (S+ for one bear), intermediate/abstract – carnivore (S+) versus noncarnivore, and abstract – animal (S+) versus nonanimal. Categories at the least inclusive and most concrete level, such as black bears or humans, contained

the most perceptual similarity within categories and less perceptual similarity between categories, making it easier to discriminate categories on the basis of perceptual cues alone. Categories at the most inclusive and abstract level such as *animals* or *nonanimals*, contained significantly less perceptual similarity within the categories. The task was a two-alternative, forced-choice (2AFC) task, where two images were presented simultaneously, side by side on the touch screen monitor and the bears were rewarded for touching images representing only one of the categories (S+). The order in which the bears received the different discriminations were varied so that one, Dusty, moved from most to least abstract while the other two tested in a pseudo-counterbalanced fashion. Importantly, most previous work on levels of abstraction ordered the discriminations from least to most abstract for all subjects, intentionally stressing the perceptual similarities within categories to the subjects. Vonk et al. (2012) were the first to suggest that perhaps presenting the more abstract categories first can aide in successfully forming those categories by reducing reliance on perceptual similarity that might occur after overtraining with concrete discriminations. The bears worked on each discrimination until they reached a criterion of 80% correct in four consecutive sessions or 90% correct in two consecutive sessions. After reaching criterion, they were presented with a novel set of images from the same two categories to test for transfer learning.

All three bears were capable of forming concepts for natural categories at all five levels of abstraction, an ability once thought to be restricted to nonhuman primates and humans. The bear that started testing with the most abstract categories outperformed the other two with regards to both acquisition and transfer on that discrimination. These findings reinforce the possibility that overtraining animals to use perceptual cues via an extensive training history with concrete discriminations could contribute to their failures to demonstrate the formation of abstract concepts in previous work (Vonk et al. 2012).

Not only did this work demonstrate that black bears are capable of forming concrete level

concepts that rely strongly on perceptual similarities, it showed that they are capable of forming abstract level concepts. Although typically observed in social species, bears likely developed this ability as a result of their diet and resultant foraging strategies. Bears are omnivores; thus, they are adept at various search strategies – dependent upon the desired target (in this case, a food item). One natural category for animals is food – a category that, for some carnivores requires a relatively concrete behavioral repertoire and search strategy, as they are reliant on hunting behaviors to obtain food (e.g., big cats). However, generalists such as ursids, may rely on a wider breadth of cues with which to make a determination regarding behaviors likely to obtain a food reward. The broad range of category differentiation in order to locate and determine what constitutes food may contribute to the capacity for discriminating categories at a more abstract level (Vonk et al. 2012).

It is important to note, however, that further research has indicated that there are some limitations to bears' abstraction capabilities. While the bears showed success using a 2AFC task, one of the same bears that previously demonstrated successful formation of abstract concepts failed to do so using a match-to-sample (MTS) task (Vonk and Jett 2018). In these tasks, a single sample image was presented, then that same image was presented along with a different image after a very brief delay. The bear was reinforced for choosing the image that matched the sample image. This task requires the animal to extract a general (abstract) rule to determine what is correct (i.e., the sample is the target). The bear was not capable of discerning that general rule, thereby failing to demonstrate abstraction in this task (Vonk and Jett 2018). It should be noted that only a single bear received extensive training in this task, and apes also failed to learn MTS after extended training (Vonk, unpublished data).

Vonk and Jett (2018) also presented two black bears with a list memory task that required them to select three images that had just been presented from a group of images that included these three test images, along with images from two other unrelated categories. Each bear was randomly assigned a training set of images from one of

five categories: Shrek characters, SpongeBob characters, sports cars, Spiderman, and computer motherboards. The three images from each category appeared in random locations within a grid of six other images from untrained categories. The task for the bears was to choose only the images they had previously seen in training to get rewarded. As an example, one bear was given Shrek images first with Spiderman and sports cars as distractors. His task was to touch only Shrek images during the test phase. Upon reaching criterion on the first set, he was trained with Spiderman as the target stimuli and SpongeBob and sports cars as distractors. In order to be successful in the subsequent tests, he would need to extract (abstract) a general rule regarding the relationship between correct selections and what he previously learned about getting reinforced (e.g., touch the images from the training category to get rewarded). Both bears failed to clearly demonstrate this capacity to abstract a rule of category membership in this task, suggesting that there could be limitations to bears' abilities to form abstract concepts, some of which are based on task complexity (Vonk and Jett 2018). However, these results from a limited number of subjects stress the necessity of testing a larger number of subjects as well as a wider variety of species.

***Social Concepts at Varying Levels of Abstraction*** Vonk and Johnson-Ulrich (2014) expanded upon this work and investigated the American black bears' ability to form concepts for the social concept of mothers and offspring. Their performance was compared to that of chimpanzees – a more social species. The same 2AFC procedure was used to test these discriminations in both species. The categories varied in inclusivity with a discrimination consisting of conspecific (same species) mother/offspring images paired with images consisting of the same species representing other social relationships. The next discrimination for all subjects consisted of primate mother/offspring groups paired with other groups of primates. Lastly, all subjects were presented with animal mother/offspring groups of varying species with other social relationships of a diverse group of species (e.g., birds, snakes).

The subjects were also presented with nonsocial category discriminations to test if a general rule other than the construct of a social relationship was being utilized. Specifically, it could be argued that instead of representing the mother/offspring relationship, the subjects could be using a perceptual rule of choosing the image of the larger animal paired with smaller, visually similar animal. The nonsocial category examined produce groupings (berries, vegetables/mushrooms, and fruit) that mimicked the perceptual patterns described above with the “mother/offspring” groups depicting one piece of produce that was clearly perceptually larger than the others in the image and the paired image that did not follow that rule (Vonk and Johnson-Ulrich 2014).

All subjects were reinforced for choosing the mother/offspring pairings in both the social and nonsocial conditions. Importantly, the goal was not to teach the animals the concept, but to assess whether that concept was something they were innately capable of representing. The researchers predicted that the social species, chimpanzees, would outperform the more solitary species, black bears, in the social tasks. However, the authors noted that, if a perceptual rule was being used to discriminate the categories, then there might not be a significant difference in performance between the species. Additionally, black bears, like many others in the family Ursidae, experience delayed ontogeny. As mentioned previously, this extended period of development could be related to cognitive advancement as has been seen in more traditionally considered social species, like primates and corvids. In this sense, bears could be argued to be fully capable of distinguishing this specific social concept, whereas others, like dominance, may not be as relevant (Vonk and Johnson-Ulrich 2014).

Interestingly, neither the bears nor the chimpanzee in this study showed clear evidence of a social concept of mother/offspring. The bears were generally unsuccessful at generalizing the concept in the social tasks and it was not clear that they were abstracting the general perceptual rule of “choose the image with the larger and smaller one(s).” The chimpanzee, however,

appeared to use the perceptual rule at least initially to succeed on the tasks, but indicated some use of the social concept as he moved through the transfer and control images. Both species, however, did not excel at this measure of the concept, which is not necessarily unexpected considering the use of static, two dimensional (2D) images. It is unlikely these species do not have a concept for mother/offspring relationships at all, but it is likely that these relationships are determined in nature by a wide variety of perceptual cues, including visual, auditory, and olfactory cues. The images in the current task failed to adequately portray this complexity; therefore, both species found it difficult. The chimpanzee, however, was more successful, indicating at least some advantage of sociality in this task (Vonk and Johnson-Ulrich 2014).

**Picture Object Recognition** One criticism of the use of 2D images for testing concepts in animals is how much information they can extract from those images in comparison to experiencing the stimuli in real life. For example, 2D stimuli fail to depict behavioral and vocal cues as to mother/offspring relationships that would be present when interacting with live individuals (Vonk and Johnson-Ulrich 2014). To determine the extent to which bears might view 2D stimuli as representative of real-life objects, Johnson-Ulrich et al. (2016) investigated picture-object recognition in an adult, captive-raised American black bear. Objects were randomly paired and one was set as the S+ and the other was the S-. The bear was trained to choose the S+, but the modality of the stimuli varied from session to session. In some sessions, the bear experienced the pairs in pictures while in other sessions, the bear experienced the pairs as real objects. If the bear was trained on pictures of the items, testing for transfer was done with real items. If the bear was trained on real items, testing for transfer used pictures (Johnson-Ulrich et al. 2016).

The subject was found to be capable of recognize the correspondence between pictures and objects, both when they were first trained as real objects then tested as images and when they were trained as images first then tested as real objects.

Notably, it appeared to be easier for the bear to transfer from real objects to pictures than from pictures to real objects. This finding is important to studies using 2D images as stimuli in cognitive tasks as it lends support to bears' ability to extract visual information from photographs that represent the objects in real life (Johnson-Ulrich et al. 2016). While this study was conducted with only a single bear, it provides support for the use of 2D images to test cognitive abilities in bears and provides further insight into the cognitive capacities of bears.

**Quantity Estimation** Vonk and Beran (2012) investigated another cognitive capacity in American black bears: the ability to discriminate quantities (larger and smaller amounts). As bears are generalist foragers, it could be argued that the ability to determine if a food patch has a larger relative amount of food, would be beneficial to survival. Especially considering the fact that bears must obtain a large amount of calories in a shortened period of time in order to be able to survive hibernation, this ability to quickly and efficiently gain those calories by preferring areas with higher density of food (larger amounts) seems like a beneficial skill. The researchers in this study used the same adult, captive-raised bears as were included in the previous studies of natural and social concepts (Vonk et al. 2012; Vonk and Johnson-Ulrich 2014) on a similar 2AFC task, but instead of discriminating category membership from photographs, the bears were tested on their abilities to judge smaller (S+) from larger (S-) quantities (two bears – Bella and Dusty) or larger (S+) from smaller (S-) quantities (one bear – Brutus).

The methods used were based on testing previously done with primates (e.g., Beran 2008); therefore, the results are truly comparative in nature. The stimuli used, filled circles (henceforward called dots) varied in size (diameter) and quantity. They also could vary in color (red or black). Different subsets could be created in the stimuli where, for instance, only the color indicated the dots to be quantified by the bears. Additionally, the sets could also vary by

amount of space (area) the dots took up on the screen. Trials could either contain dots that were congruent between size and quantity, indicating that the larger quantity also represented more space on the screen (and vice versa for the smaller quantity) or the dot array could be incongruent, where the larger quantity actually took up a smaller amount of screen space than the smaller quantity. These differences were important to ensure that numerosity (indicated by the number of stimuli present), not quantity (indicated here by the area presented on the screen), was the cue most associated with the determination of which stimulus was larger or smaller (Vonk and Beran 2012).

All subjects reached above chance levels of performance, eventually, but the time it took to reach criterion on the different tasks varied significantly by both individual and task. The bear that was trained to choose the larger quantities, performed best with congruent dot arrays (where the larger quantity also took up more space) on the static and moving images. However, he relied heavily on area for the moving stimuli, indicating that judging quantity in static arrays is less taxing than in moving arrays. He was capable of judging the larger quantity in both congruent and incongruent trials in the moving subset trials, though, suggesting that the ability to judge number in dynamic sets is not completely absent. For the two bears that were trained to choose the smaller number of dots, their success was limited to the incongruent trials (meaning the smaller quantity of dots took up more space than the larger quantity). These results imply that they relied heavily on area and less on number. Taken together, the results of the experiment indicate that judging larger quantities relative to smaller quantities is easier for the bears, as indicated by the fact that the other two bears had such difficulty learning their task of choosing the smaller quantity in all conditions (Vonk and Beran 2012). These results probably reflect the adaptive value of preferring larger quantities of food, which would allow for the highest intake of calories with the lowest expenditure of energy possible. An early study of food preferences in black bears found that they preferred foods high in protein and carbohydrates across seasons (Bacon and Burghardt 1983).

**Spatial Cognition** Many of the previously discussed studies cite bears' diets as a possible ecological force in the evolution of cognitive skills. Because of their omnivorous diet, bears must exhibit a high degree of behavioral flexibility to obtain food in a variety of contexts, including foraging, hunting, and scavenging – all of which occur in a wide range of contexts depending upon environment, prey species, learned associations, and other factors. In order to effectively forage, hunt, and/or scavenge at a moment's notice, bears must rely on a wide range of cues, search strategies, and strategy in order to locate food.

There are many foraging strategies that animals utilize, including extractive foraging, in which a tool or appendage is inserted into something in order to extract the contents (e.g., a chimpanzee using a stick to get termites from a mound). Extractive foraging is contrasted with non-extractive foraging, where the animal finds food that is out in the open or not contained within something (e.g., a bear finding berries on a bush). Bears use both extractive and non-extractive foraging techniques but have not conclusively been shown to be tool-users (see next section for a possible exception). In the wild, bears are known to occupy home ranges and oscillate between productive patches seasonally, in order to maximize foraging efforts, as well as seek out mates and evade potential conflicts with other bears (Apps et al. 2004). Additionally, bears are known to cache large amounts of food – particularly following predation on a large ungulate or other prey species – to which they return later to feed (Elgmork 1982). This aspect of their foraging ecology, along with their large home range sizes, suggests that they should demonstrate good spatial memory.

One test of spatial cognition involves spatial memory, where subjects are shown baited locations, either in real life or a simulation, and then asked to recall those locations either immediately or after some time delay. Two studies, one with giant pandas and one with American black bears, investigated bears' ability to remember the spatial location of stimuli, but using different

methodologies. Perdue et al. (2009) used a 2x3 light grid to test giant pandas on their ability to recall which lighted location was associated with a reward (food). Essentially, the bears were shown a lighted grid with a light of specific brightness indicating the location of the reward. The grid was then darkened and the bears were to respond by indicating the location of the light associated with the reward in order to be reinforced and receive the food reward. Both pandas tested were capable of learning the task, indicating some evidence of spatial working memory in bears (Perdue et al. 2009).

Zamisch and Vonk (2012) employed a spatial memory task using baited locations within the enclosure of four adult, captive-raised American black bears to investigate their capacity to recall the locations of baited sites. The experimenters set out with the goal of using eight possible sites with four sites baited. This number was reduced to four with two sites baited for two of the three experiments conducted to reduce memory load and task complexity. They were interested in several factors that could impact recall, including time delay between learning and recall, the impact of competition through the influence of a knowledgeable foraging partner. It was predicted that, as the time between learning and recall increased, fewer sites would be recalled. Additionally, search strategies were investigated with the prediction that there would be some form of systematic search strategy that emerged (e.g., minimizing distance to the baited sites by bypassing closer, unbaited locations during the recall test). It was also of interest, in the knowledgeable partner condition, to see if the bear who had experience with the sites during the learning phase changed their behavior in any way when there was competition (e.g., using a more systematic search strategy to increase probability of obtaining food) (Zamisch and Vonk 2012).

Overall, it was found that the bears did not forage efficiently by first approaching baited sites. Only one of the four demonstrated that if the same sites are repeatedly baited over several sessions (rather than changing each session), she was capable of bypassing unbaited sites for baited sites that were a longer distance from the start

point. This capacity, however, was not clearly demonstrated in the other subjects (Zamisch and Vonk 2012). Vonk et al. (2015) demonstrated similar findings in grizzly bears, who demonstrated no evidence of learning as a result of either spatial or visual cues. It would, however, be problematic to draw the sweeping conclusion that bears do not possess spatial working memory based only on the results of these experiments. A major limitation of any study done in captivity is the lack of ecological pressures that could drive cognitive development. Bears in captivity have a limited range due to the constraints of their enclosures in comparison to their wild counterparts. As Zamisch and Vonk (2012) indicate, it could be that the total size of the bears' enclosure in this experiment likely represents one medium-large food patch in the wild. This is due to the fact that there is no need to search efficiently when little energy is required to search all possible sites. Additionally, there are no real pressures to forage for food in captivity as it is freely given to them, usually in a centralized location. These ontological (developmental) factors could impact the expression of spatial memory skills (Tarou 2004; Zamisch and Vonk 2012). As with most work done in captivity, replication with wild populations and in a wide variety of captive settings is vital to fully understanding this capacity in bears.

An important aspect of spatial memory is the capacity for object permanence (objects continue to exist if no longer in sight) and short-term memory (STM). It would appear that one of the shortcomings of the bears in Zamisch and Vonk's (2012) study was the inability to hold the spatial locations in their minds after a delay, an ability that is made possible via STM. To understand bears' ability to follow the locations of invisible objects, Hartmann et al. (2017a) tested Indian sloth bears (*Melursus ursinus*) and Bornean sun bears (*Helarctos malayanus euryspilus*) on three traditional spatial cognition tasks. The first task measured basic object permanence in a task, also known as the "shell game", used with both human children and a wide variety of nonhuman animals. In the simplest form of this task, two inverted cups are placed in the view of the subject. A food

reward is shown to the subject then hidden, while the subject is watching, under one of the two cups. The subject is then allowed to make a choice to indicate where they think the food was hidden. Both species made the correct choice at above chance levels, so it was determined they possessed object permanence. A similar study was conducted with sloth bears using a three choice paradigm and holes in a large log to increase ecological validity, mimicking extractive foraging. The bears performed above chance only when allowed to search immediately or when provided with acoustic cues but not after relatively short delays, leading the authors to conclude that they had object permanence but poor STM (Amici et al. 2017).

STM was measured by Hartmann et al. (2017a) in the two species previously described using a spatial transposition task called the visible displacement task. This task measures the spatial transposition skill of rotation and involves two different degrees of transposition: 180° and 360°. In the 180° transposition, task, two inverted cups are placed on a tray in front of the animal. Food is then hidden under one of the two cups while the animal watches. After the food is hidden, the experimenter then rotates the tray 180°; therefore, the baited location is on the opposite side of the tray. In order to be successful, the animal must have followed the baited cup to its new spatial location and recalled that when given the opportunity to choose during the test. On this task, the sloth bears and only one of the sun bears were successful, indicating that the ability to follow 180° rotations, while more challenging than no transposition, is possible in these groups and that they have the STM capacity to hold spatial information in their minds during these movements (Hartmann et al. 2017a). Further work is needed to reconcile their findings with those of Amici et al. (2017).

Lastly the researchers introduced a 360° rotation task, which included both a reverse and an orbital rotation. In the reverse rotation, the two cups were rotated 180° as in the previous experiment, but then rotated back to their original positions by moving them in the opposite direction by 180°. The orbital rotation rotated the baited cup

180° then continued the path in the same direction until the bait was back in its start position. Only the sloth bears were tested on this experiment, but they were successful in recalling the location of the bait after both the reverse and orbital rotations (Hartmann et al. 2017a). Taken together, these results provide support for the assertion that bears possess the base requirements for spatial memory, despite other bear species not consistently demonstrating other types of spatial memory (e.g., Vonk et al. 2015; Zamisch and Vonk 2012). Bears appear to outperform domestic dogs in the 180° transposition task as dogs, when given a three-choice task, were not consistently successful at following the 180° side rotation that resulted in the bait ending on the opposite side to its start position (Broadway et al. 2017). Perhaps domestication impacted dogs' abilities in comparison to the ecological pressures experienced by bears, despite the two groups having the largest brain to body size ratio of all other mammalian carnivores (Benson-Amram et al. 2016).

**Tool Use and Problem Solving** Tool use was long believed to be restricted to humans, then extended only to certain great apes, like chimpanzees. However, our knowledge of tool use capabilities in nonhuman animals has grown vastly over the past few decades, expanding to many species of mammals outside of the primate order (e.g., otters, elephants, and dolphins) as well as several bird species (e.g., crows and finches) and even invertebrates like octopi. One of the issues within the study of tool use is that the definition of what constitutes tool use is not always agreed upon by researchers. A relatively basic agreed upon definition of tool use includes the use of an object external to oneself to manipulate another object (e.g., an otter using rocks to pry open a bivalve) or something on one's own body (e.g., a person using a brush to comb their hair, Deecke 2012).

Bears, however, are understudied in the area of tool use. There is some evidence of tool use in captive brown bears (Waroff et al. 2017), along with a reported failure in sloth bears in a similar

paradigm where bears had to maneuver an object under a hanging food reward to retrieve it (Amici et al. 2017). One observation from a wild Alaskan brown bear (*Ursus arctos*), provides an example of what appears to be spontaneous tool use when a subadult male brown bear was documented picking up a rock with barnacles on it, grasping it with its paws and claws, then using it to rub its face. This behavior was repeated three times with different rocks during the same observation period. It was suggested that the bear was using the barnacled rock as a grooming aid after consuming oily remains of a whale (Deecke 2012). Observations such as this suggest that bears may be capable of tool use, as it is currently defined in the literature (see the Bear Management chapter for more information on wild ursid behavior).

As with tool use, the ability to flexibly solve problems has also been heralded as a sign of advanced cognitive evolution. Benson-Amram et al. (2016), argued that it is relative brain size that is related to problem solving, with those species that have larger relative brain to body sizes possessing more sophisticated cognitive skills in comparison to those with smaller relative brain to body sizes. This hypothesis, in essence, links relative brain size with intelligence. Within most taxa, there is a wide variety of relative brain to body size ratios, with some having larger and some having smaller ratios. The Carnivore order fits that description, with Ursids and Canids having the largest relative brain to body size and Viverrids (civets and genets), Hyaenids (hyenas), and Herpestids (mongooses) having the smallest brain to body size ratios of the order (Benson-Amram et al. 2016).

Given that information, it could be predicted that, given a problem-solving task, species with large relative brain sizes should outperform species with smaller relative brain sizes. If, however, sociality impacts the development of these skills instead, then species with higher degrees of sociality (e.g., hyenas) should outperform species that are less social (e.g., bears), despite their differences in relative brain size. Problem solving ability can be measured in many ways. Benson-Amram et al. (2016) used a puzzle box that had a

slide-bolt secured door that had to be pulled back to release the door and allow for retrieval of the food reward inside the box to test 140 individuals representing 39 species within the order Carnivora. They accommodated for the wide variety of sizes of differing species by creating a small and a large box. Success was defined as opening the door by any means (e.g., sliding the bolt or moving the box until the door came open). It was found that the most successful groups, overall, were Ursids, Procyonids (e.g., raccoons, coatis, and kinkajous), and Mustelids (e.g., otters, ferrets, and badgers). Herpestids were the least successful group at opening the puzzle boxes. Their analyses showed that other factors (e.g., sociality) were not related to success in opening the box; only relative brain size showed statistical significance as it related to likelihood of success, with species with larger relative brain to body sizes succeeding that the task more often than those with smaller relative brain sizes, supporting their hypothesis (Benson-Amram et al. 2016).

However, it is important to note a few things when examining these conclusions. One is that this study narrowly defined sociality as living in large, complex social groups throughout development. It neglects the concept of delayed ontogeny, which many of these species exhibit, and has been linked to providing the time for the development of larger brains as well as opportunities for social learning. Therefore, the development of a larger relative brain size is confounded with social factors, like delayed ontogeny. Additionally, the authors used a narrow definition of success by using a dichotomous measure - either opening or failing to open the box. It is possible that other outcomes, such as time it took to solve the task or persistence, might have provided more inclusive measures of problem-solving abilities. Benson-Amram et al. (2016) also failed to account for ecological factors, such as use of extractive versus non-extractive foraging and diet, in their analyses, leaving room for many other possible contributing mechanisms that impacted success or failure (Vonk 2016). While this study was the first of its kind in terms of breadth of species, more work is needed to conclusively determine the mechanisms at play.

**Self-awareness** Thus far, we have focused on aspects of physical cognition. Unfortunately, there is very little work addressing social cognition in the relatively solitary ursids. However, there is at least one study investigating mirror self-recognition (MSR), or the ability to recognize oneself in an image created by a mirror. MSR develops over time in humans, with the human infant first lacking the ability, but with time and experimentation, they learn that what they see when they look in a mirror is not a conspecific, but their own reflection. Consistent with hypotheses outlined above, species that are both highly social and have larger relative brain size have tended to demonstrate MSR when tested via the mark test. The mark test involves placing a mark of some type (e.g., paint) on the individual's face, or other area not easily seen without the assistance of a mirror, and then providing the opportunity for the individual to investigate their reflection in a mirrored surface. Researchers then record how the subjects interacts with the mirror and watch for any mark-directed behaviors, indicating that the subject recognizes that the reflection in the mirror is themselves and the mark is an anomaly to their typical appearance. In a study conducted with giant pandas (*Ailuropoda melanoleuca*) using the mark test, it was shown that the pandas fail to recognize the image in the mirror as themselves, instead responding in a manner that indicated viewing the image as a conspecific, with some acting in an aggressive manner upon first inspection of the reflection (Ma et al. 2015). This is similar to the reaction of many primate species including monkeys and prosimians (Paukner et al. 2004).

A major criticism of all MSR tests with non-humans is the ecological validity of a mirrored surface. In nature, coming across a clear pool of water is likely to be the only time an animal might encounter their own reflections, rendering the ability to recognize their reflection in a mirror unnecessary or irrelevant. It is possible that, in these cases, they simply ignore their reflections entirely as they are missing other perceptual cues (e.g., olfactory or auditory) to indicate the presence of a conspecific and have no need to be

concerned with the reflection (Ma et al. 2015). However, to date, giant pandas are the only bear species to be tested on MSR, so conclusive evidence is not present for the lack or presence of MSR in bears. However, it is also possible that visual cues relating to one's own reflection is not salient to the majority of wild animals in the context of their evolutionary history, as was suggested by Horowitz (2017) who demonstrated that dogs are able to differentiate between their own odor and that of another dog, and investigate their own scent signature for a much longer period of time if it has been altered. Thus, according to Horowitz, there is a need to determine self-awareness in a biologically relevant manner. This has not been investigated in ursids, to our knowledge. However, this approach does have interesting implications for this area of study. It is possible that the research community simply needs a new way to ask this old question, that is more biologically relevant to the target species.

**Conclusions Regarding Basic Research on Bear Cognition** The work presented in this entry represents only a summary of key findings regarding our current knowledge on bear cognition. However, the simple fact remains that more work is needed to fully elucidate the inner workings of the ursid mind. The vast majority of what we know about bear cognition has been driven by a few individuals of approximately five different species. Most of the work discussed here, has been done with animals born and raised in captivity. We are well aware of the potential positive and negative impacts captivity can have on animals. In order to truly understand the species, we must work to overcome the challenges and test wild populations.

## Synonyms

Olfaction; Scent; Signals; Ursid communication; Vocalization

## Introduction

There are eight extant species of bear in the order Carnivora. Bears inhabit a wide variety of habitats on every continent except Africa, Australia, and Antarctica and are largely solitary, although they may temporarily aggregate at a concentrated food source or during breeding. Bears employ four primary modalities of communication: olfactory, visual, auditory, and gustatory signaling. Of these, olfaction seems to be the most important and the best-studied across all eight species of bear. Scent marking uniquely allows animals to communicate remotely, over time, with multiple other animals, thus allowing them to avoid potentially energetically expensive physical conflict. Solitary species like bears may benefit from advertising their location and reproductive status to expedite mate selection during the breeding season. Throughout the rest of the year, communication of this information could facilitate temporal avoidance by conspecifics, reducing competition for limited resources. The sensory systems and communication

modalities of the brown bear (*Ursus arctos*), American black bear (*Ursus americanus*), and the giant panda (*Ailuropoda melanoleuca*) are the most researched. Minimal research has been conducted on communication in the other five species.

## Olfactory Communication

Although bears are generally regarded as having an extremely acute sense of smell, it is difficult to quantify olfactory sensitivity, as the olfactory response to a stimulus is affected by numerous factors. Odorant detection may be altered by airflow to the olfactory region, which can change due to obstruction of the airway, differences in sniffing behavior, or swelling of the epithelial cells due to increased blood flow. Odorant binding to receptors may be affected by mucosal viscosity, physical and chemical properties of the odorant, and the presence of airborne particles like dust and bacteria. Experimental quantification of ursid olfactory capabilities remains a largely unexplored area of research.

### Rub Trees

One of the main ways that ursids communicate via olfaction is by marking rub trees by rubbing their bodies against them or by clawing or biting the bark of the tree, often leaving fur, frayed bark, and scars on the tree trunk (Burst and Pelton 1983; Taylor et al. 2015). Rub trees may be used for generations (Schaller 1985). Rubbing behaviors may deposit secretions from sebaceous and apocrine glands, while clawing may leave scent from pedal glands. Biting may deposit saliva, and urination and deposition of anogenital gland secretions (AGS) may also be important forms of communication (Clapham et al. 2013). All species except polar bears (*Ursus maritimus*) have been observed using rub trees (Burst and Pelton 1983; Clapham et al. 2013; García-Rangel 2012; Laurie and Seidensticker 1977; Schaller 1985). Scent-marking behaviors performed at rub trees vary with species, age, and reproductive status (Clapham et al. 2014) but typically include two or more of the following actions, often in the order listed: (1) investigating the tree; (2) rubbing the head, neck, and/or

shoulders on the mark tree; (3) rubbing their sides against the tree while in a quadrupedal stance; and (4) turning away from the tree bipedally to rub their backs and necks (Clapham et al. 2014; Taylor et al. 2015). Trees may be damaged by clawing, biting, and intense rubbing, sometimes resulting in tree breakage and death (Burst and Pelton 1983).

Scent marking is not without energetic cost. The time and energy spent marking could detract from other activities, like foraging and reproduction (Nie et al. 2012). To minimize this cost, bears must select objects that will readily attract the attention of the signal receiver. Rub tree selection varies between species. A study conducted on spectacled bear (*Tremarctos ornatus*) scent-marking behaviors showed that bears mostly marked live trees but occasionally used fallen trees, dead standing trees, or wooden poles as mark sites. Many (38.8%) of the mark trees were aromatic, and 46.9% were a food source for spectacled bears (Filipczykova et al., 2016;). Brown bears may prefer coniferous trees; exuded sap may help preserve scent marks (Nie et al. 2012). A 6-year study of 116 trees in Yellowstone found that brown bears preferred to mark trees along trails, usually on the side facing the trail. The average maximum height of rub marks was 1.7 m. Only 9% of trees bore claw or bite marks. Most marking occurred between late May and July, during peak breeding season and the molt (Green and Mattson 2003). American black bears may mark trees, telephone poles, and signposts. In a study in the Great Smoky Mountains National Park, marks were most concentrated at 1.6–1.7 m off the ground, usually on the side of the tree facing the trail. Bear hair or mud were occasionally adhered to sap or bark. Mark trees that were not associated with a man-made trail were adjacent to a game trail 74% of the time. Some rub trees were up to 15 m away from the game trail, with a clearly defined path leading to the tree (Burst and Pelton 1983). Spectacled bears marked trees on average 1.7 m from ground level, using trees adjacent to bear trails and marking the sides of the trees that face the trail (Peyton 1984). The function of scent marking in this species is not yet known. However, when spectacled bears were detected via camera trap, the probability that a different bear would appear at the same site was elevated for several days, implying some

form of chemical communication. In addition to facilitating intraspecific communication, rub trees may also function interspecifically: American black bears used rub trees less after brown bear use (Shaffer 1971).

### Pede Marking

Pede marking is the process by which bears scent mark the ground by grinding their feet into the substrate, typically before or after using a rub tree. One study of black bear rub tree use in California found that black bears pede marked exclusively after scent marking a rub tree, with pede marking occurring in a third of rub tree uses (Taylor et al. 2015). Brown bears have eccrine glands on the footpads and sebaceous and apocrine glands on metatarsal/metacarpal and interdigital skin (Sergiel et al. 2017). Brown bears also sometimes engage in pede marking near rub trees (Sato et al. 2014), grinding and stomping their paws into the ground. At times these marks are clearly visible as depressions in the ground near the tree, but sometimes substrate consistency renders these scent marks invisible to a human observer (Clapham et al. 2013).

In contrast to black and brown bears, in which pede marking is often secondary to use of a rub tree, polar bears inhabit sea ice for much of the year and lack access to similar fixed marking features. In the absence of rub trees, pede marking may be a much more important form of scent marking for polar bears. Polar bears have apocrine and sebaceous glands on interdigital skin. In tests of 26 adult polar bears, males spent more time investigating interdigital scent swabs from females than from males. Male bears investigated samples from females in estrus significantly more than samples from non-estrus females during the spring breeding season and were more likely to exhibit flehmen behavior, which transfers scent to the vomeronasal organ to assess sex and sexual receptivity of the signaler (Owen et al. 2014). During the breeding season, male polar bears find mates by following females' tracks (Molnár et al. 2008), sometimes traveling 100 km or more, often while fasting for days at a time (Stirling 2011). Given the low density of polar bear populations and the immense energetic cost of such pursuit, the ability to identify estrus females

by pedal scent may be critical to a male's reproductive success. Interdigital scent glands similar to those found in polar bears were not found in sloth bear (*Melursus ursinus*) pedal skin samples (Patil et al. 2016). Additional research is needed to determine whether other species possess specialized pedal glands for marking.

### Anogenital Secretions, Urine, and Feces

Giant pandas (Yuan et al. 2004) and brown bears possess anal glands that produce secretions that may be an important form of olfactory communication in these species. There is no consensus as to which, if any, of the other six bear species has anal sacs (Rosell et al. 2011). Researchers examine how bears glean information from AGS by comparing gas chromatography results from AGS samples from different classes of bears (e.g., male or female) and looking for differences in the relative abundance of various substances and for substances that are present in one group but absent in the other. Key components of AGS should have high molecular weights. This lack of volatility ensures that scents remain where placed for as long as possible.

Brown bears' large home ranges preclude frequent scent marking, so long-lasting AGS marks would be energetically advantageous (Rosell et al. 2011). Adult brown bear AGS is not waxy like that of the giant panda (Taylor et al. 2015). It is gray or black, foul-smelling, and claylike, with male AGS tending to be darker than female AGS. Anal sacs are paired and open at the cutaneous zone of the anal canal. Sex differences were found in the relative abundance of five substances (Rosell et al. 2011). Therefore, it is possible that brown bears can distinguish the signaler's sex from AGS deposits.

Giant pandas are solitary but their home ranges overlap with those of other pandas of both sexes. Additionally, female pandas enter estrus once a year and are receptive to mating for only 24–72 hours. Therefore, chemical communication is essential to avoiding conflict and attracting mates. Pandas do not respond to urine after it is a few weeks old, but they continue to react to AGS months after collection (Swaigood et al. 2000; White et al. 2002). Urine and AGS differ in

chemical composition and may relay different information to the receiver. A gas chromatography and mass spectrometry study of AGS from 24 adult and subadult pandas of each sex indicated that these waxy secretions consist mostly of steroids and saturated and unsaturated fatty acids. Comparisons of each age-sex class revealed that age and sex may be signaled by the relative amount of each compound rather than by the presence or absence of specific compounds. The nonvolatile components of AGS may make it ideal for leaving scent marks that last for extended time periods or that serve as a delayed message (Yuan et al. 2004). There is high individual variation in the relative quantity of AGS components, as well as in the types of compounds that are present; it is possible that each panda has its own distinctive AGS signature that makes it identifiable to other bears (Zhang et al. 2008).

Male giant pandas scent mark year-round, whereas females primarily scent mark during the breeding season (Swaigood et al. 1999; Nie et al. 2012). Additionally, males spend equal amounts of time investigating male and female scent samples, while females are more interested in male scents. Therefore male scent marking likely has a variety of functions, whereas female scent marking may be exclusively related to reproduction (Swaigood et al. 1999). Males mark significantly more when exposed to female odors than when presented with male scents, possibly to increase the likelihood that their marking will be detected by the female (Swaigood et al. 2000). Giant pandas deposit urine using four different postures: squatting, quadrupedally backing into a vertical surface, urinating with a single leg raised, and while performing a handstand (White et al. 2002). This handstand posture may be used in part to place urine at nose height. Pandas rub themselves against the marking surface vigorously while AGS marking but not while urine marking (Nie et al. 2012). Females commonly squat to urinate, while the handstand posture is almost exclusive to adult males and may serve as an indicator of body size and competitive ability to conspecifics. Pandas of all age-sex classes spent more time investigating adult male urine placed 1 m above ground level than when the same urine

was presented at ground level or when female urine was left in the same locations. Pandas, especially subadult males, also stayed farther away from the elevated male scent mark, possibly to avoid a potentially costly interaction with a large, more dominant animal (White et al. 2002). Captive adult males performed the handstand posture less frequently when in another animal's pen than when they found another animal's scent in their own enclosure. Given that pandas are quasi-territorial, this bolsters the conclusion that handstand urination is a range-marking behavior. An intruding animal would avoid provoking conflict with the resident by minimizing marking, whereas resident pandas would be motivated to reinforce their scent markings when confronted with an unfamiliar male's scent (Swaigood et al. 2000).

Giant pandas scent mark with AGS in addition to urine, typically while following ridgelines (Nie et al. 2012; Schaller 1985). A 1-year study of 6.9 km of such ridges found that 11.5% of eligible trees within 1.5 m of the trail bore panda scent marks (urine, AGS, or both). Pandas chose trees with the roughest bark for urine marking and preferred rough-barked, moss-free trees for AGS marking. It is possible that extremely rough-barked trees were selected for urine marking to prevent the urine from flowing down the tree or being quickly removed by rainfall. Of the 2186 available trees, 219 were marked with AGS, 34 were marked with urine, and 5 trees bore both marks. 38.3% of mark trees were remarked at least once. Most marks were deposited in February during the main breeding season or in November when a second breeding cycle sometimes occurs (Nie et al. 2012).

Olfactory cues can alter male sexual behavior. In a study of 11 male giant pandas, scent (AGS and urine on fir bark as well as feces) from one or multiple other male pandas was placed in each panda's home pen during the breeding season; control group males were presented with unscented fir bark and their own feces. Females in estrus were housed in alternating enclosures between males, and each male was randomly assigned to one of the three treatment groups every 2 days. Males exposed to odors from other males spent more time investigating their

environment and observing, following, and sniffing females. No differences were found in scent-marking behaviors, bleating, or footscraping. The increase in most female-oriented behaviors and the lack of change in territorial behaviors support the observation that wild male pandas pursue females and fight competing males; given the brevity of the female receptive period, mate-guarding is likely a more successful strategy than territorial behaviors (Bian et al. 2013).

Social context alters panda reproductive behavior during the breeding season. Adult female pandas typically signal most prolifically during peak estrus, but females housed in an enclosure between those of two other female bears signaled less than bears housed with at least one male neighbor or with no neighbors. Similarly, among captive female sun bears (*Helarctos malayanus*), 70% of those housed with a male bear entered estrus at least once per year, while 66.7% of females housed alone or with another female failed to cycle (Frederick et al. 2013). The presence of other females may inhibit signaling behaviors, allowing the focal female to conserve energy by not broadcasting to inappropriate receivers (Owen et al. 2016).

Bears may use olfactory cues to avoid inbreeding. Female panda cubs that had been raised with their mothers for 6 months, then reared separately for 5–6 months, spent more time investigating urine and body odor from unfamiliar adult female bears than they did examining their mother's scents. Mother bears also spent more time inspecting scents from unfamiliar age-matched cubs than they spent on odors from their kin. This suggests that pandas remember the scents of their kin and/or that they use self-referent phenotype matching (the “armpit effect” – comparing their own phenotype to a new odor) to identify unfamiliar bears. Female pandas disperse upon reaching maturity, while males remain closer to their mother's home range. It is possible that females use scent recognition to avoid female relatives in selecting their new home ranges, thus avoiding inbreeding with their father, as male home ranges overlap those of their mates (Gilad et al. 2016). One study of panda urine and AGS found that kinship odors – compounds present in urine and AGS that

correspond to genetic relatedness – were detectable only in male scent marks during the breeding season (Liu et al. 2008).

Male American black bears use olfactory cues to assess a female's receptivity to mating. Gonzales et al. (2013) found that semi-free ranging males sniffed the female's urogenital region in over 80% of interactions that led to the male mounting the female. Males also smelled urine and feces from females, often exhibiting a flehmen response that suggests vomeronasal involvement. Males mated with females most frequently when females were in peak physiological estrus. Additionally, during the Gonzales study, male bears abandoned mounting attempts in 53% of unsuccessful encounters, providing further evidence that males can detect a female's receptivity to mating. Eight of the 11 females studied displayed temporally synchronized estrus; while this is usually not observed in wild bears, it could indicate that females are able to detect conspecific reproductive status via chemosensory cues (Gonzales et al. 2013). In breeding pairs of brown bears, males often smell the female's genitalia, which may offer scent cues as to her reproductive status (Steyaert et al. 2012).

## Visual Communication

Ursids are often said to have poor visual acuity, but little research has been done to confirm this assertion. An American black bear successfully discriminated objects of differing shapes and sizes, even when the positive stimulus had been rotated and when the background color was changed (Bacon 1973). Some ursids have color vision. Giant pandas can discriminate green and red from gray. Females can also see blue; male bears have not been tested (Kelling et al. 2006). L-cones and S-cones are present in polar and brown bears, indicating that these species may have dichromatic color vision (Peichl et al. 2005). American black bears have at least some hue discrimination; their ability to tell blue and green from gray indicates that they have more than monochromatic vision (Kelling et al. 2006).

Visual signals only last as long as the sender is signaling. In bears, visual signals often take the form of body postures, which may serve as ritualized displays that allow individuals to avoid injury or behavioral displays. For example, male American black bears posture during the breeding season, sliding their front paws smoothly over the ground with stiffly held front legs in the presence of females in estrus or other males (Boone et al. 2003). Bears may charge other animals when threatened and may or may not make physical contact; sloth bears may charge or chase unfamiliar bears or other animals when they approach too closely (Joshi et al. 1999). American black bears may also lunge forward, simultaneously swatting the ground with their paws and exhaling explosively (Jonkel and Cowan 1971).

Behavioral displays are very important to the reproductive process of giant pandas. In the wild, as a female panda enters estrus, multiple males gather to court her. She avoids them until she is ready to breed, sometimes by climbing a tree. Captive male bears exhibited relatively constant courtship behaviors toward females throughout the estrus cycle, while female pandas switched from aggressive displays to increasingly proceptive and receptive behaviors as they approached peak estrus. Aggressive behaviors included paw swatting and charges in addition to threatening or defensive vocalizations; behaviors exhibited by females at peak estrus included approaching the male, walking backward, presenting the hindquarters to the male, and lordosis. Only females showed mixed aggressive and affiliative behaviors – i.e., alternating aggressive and affiliative vocalizations or making sounds containing elements of both types of vocalization. As this behavior was seen frequently in female pandas near peak estrus, it may be a signal to males that the female is nearly ready to mate (Owen et al. 2013). Non-behavioral visual cues may also contribute to the courtship process. As female American black bears enter estrus, their vulvas become engorged and inflamed. Males may visually assess the vulva of a female to determine reproductive status (Gonzales et al. 2013).

Spectacled bears have spectacle-like, often asymmetrical markings on their faces that can extend down the animal's chest. However, these

markings are not reliable indicators of age, sex (García-Rangel 2012), or kinship. In this species the nose becomes pinker as the bear ages (Van Horn et al. 2015), so nose pinkness could signal an individual's age to other bears, although this has not been confirmed experimentally. It is possible that spectacled bears learn individual patterns of markings to identify familiar bears. Pandas can discriminate between panda face-like masks, indicating that color patterns may facilitate individual recognition (Dungl et al. 2008).

## Auditory Communication

Sound can transmit complex signals long distances quickly, although signal persistence is low, and this type of signal is not necessarily easy to locate. As bears are generally solitary, non-territorial mammals, they usually use auditory signals at close range. One unusual manner of vocal communication exhibited by bears is “humming,” a sound produced mostly by cubs but sometimes by adults, generally in association with nursing, contentment (Kenny and Bickel 2005; Derocher et al. 2010), and sucking (Peters et al. 2007). Sun bear cubs hum, squawk, croak, and whine (Hall and Swaisgood 2009). Giant pandas are the only ursid that does not hum. Humming consists of a bear making short, single, usually monotonous sounds every 0.1 s punctuated every 3.5–10 s by inhalation (Peters et al. 2007). Cubs also produce screaming or crying vocalizations, which are often preceded or followed by sounds associated with discomfort (Kenny and Bickel 2005; Van Gessel 2015). Van Gessel (2015) observed that screaming seemed to stimulate captive mother polar bears to respond to their cubs; a dying cub vocalized less and less and thus received less care, which may have contributed to its death. Because disturbance may cause hibernating bears to abandon their dens, wild mother bears and cubs are usually studied only after they emerge from the den. Therefore, most studies of denning mothers and cubs are conducted on captive animals and may not be representative of wild animals.

Sloth bears may growl when threatened by another bear (Joshi et al. 1999). They roar when

fighting other bears, and a scream-like call is emitted during fights. Cubs yelped when separated from their mothers, prompting their mothers to return to them; treed females with their cubs on the ground made a grunt-whicker. Sloth bears huff, possibly as a warning sound. Sloth bears also make chuffing-like sounds, often while retreating from a disturbance. Bears foraging for termites and other invertebrates make characteristic sucking and blowing noises that may advertise the bear's location, facilitating avoidance of other animals (Laurie and Seidensticker 1977). Brown bears have also been described as huffing, growling, and roaring, as well as woofing and bawling (Egbert 1978).

Courting pairs of American black bears used several modes of auditory communication. Courting males quickly blew air through their mouths to produce sound when another male approached a female in estrus, apparently to deter the newcomer. Both males and females made clicking and popping sounds with their jaws and throats during courtship (Boone et al. 2003). Giant pandas also use vocalizations to communicate during the breeding season. Pandas may be able to distinguish males from females using the formant frequencies in the other panda's bleat or the interaction of the formant with other elements of the call; low formants correspond to large body size and therefore to male pandas (Charlton et al. 2010b). Each panda's bleat is highly acoustically distinctive and may be used in individual recognition or possibly in distinguishing kin from unrelated bears (Charlton et al. 2009b). Non-estrus female pandas primarily rely on amplitude modulation to tell bleats from different males apart (Charlton et al. 2009a). Fertile females produce harsher, longer chirps than pre-fertile females, and males approached and remained near playback speakers significantly more after hearing calls from fertile females than after hearing calls from pre-fertile females (Charlton et al. 2010a). This distinctive chirp vocalization may be unique to the giant panda (Schaller 1985). Estrus females vocalized more than non-estrus females upon encountering male scents, and, similarly, males vocalized more in response to estrus female odors than to scent marks from nonreceptive females

(Swaigood et al. 2000). However, another study of adult pandas (10 females and eight males) found that, during the breeding season, males increased marking behavior in response to a playback of bleats from a female in estrus. Females in estrus did not alter marking behavior upon hearing recorded bleats from a male during the breeding season. In this study neither sex was found to alter its vocal behaviors in response to bleat playback (Xu et al. 2012). These studies all featured captive animals that may have already been somewhat familiar with one another; further study of wild pandas is necessary to confirm these results.

## Gustatory Communication

Taste may be an important form of communication for bears during the breeding season. Male American black bears licked (and sniffed) females' urogenital areas during courtship, apparently to assess the female's reproductive status (Boone et al. 2003). Courting males also licked urine and feces deposited by females, sometimes while the female was urinating (Gonzales et al. 2013). Both male and female giant pandas lick scent deposits from conspecifics. Males licked female chemosensory stimuli more than they did male stimuli, which may indicate that they are using nonvolatile chemical components of the scent to assess female reproductive status (Swaigood et al. 2000).

## Conclusion

Ursids use visual, auditory, gustatory, and olfactory signaling to communicate with other animals. Olfaction seems to be the most important channel through which bears signal. Olfactory signals differ between species and include the use of rub trees, pede marking, urination, defecation, and AGS, which may allow bears to convey information about sex, reproductive status, and location to other animals. Ursids may also use taste to examine scent deposits. Visual signals include diverse postural displays that allow bears to communicate physical and reproductive fitness from a distance.

Bears make a variety of vocalizations which can be used as threats during agonistic encounters, to advertise sexual receptivity, or for communication between a mother bear and her cubs. The communication modalities of brown bears, American black bears, and giant pandas have been relatively well studied, but further research is needed in the remaining five species, and experimental manipulations of captive animals must be validated by studies of wild bears.

### Feeding habits

## Introduction

The variety in the diet of the eight bear species reflects their wide-ranging habitats, from the desert to the Arctic and from the coast to the mountains. Although bears are omnivores, there is a dietary range from mostly herbivorous (e.g., the giant panda (*Ailuropoda melanoleuca*)) to mostly carnivorous (e.g., the polar bear (*Ursus maritimus*)) and from generalists (e.g., the brown bear (*Ursus arctos*)) to specialists (e.g., the giant panda). Nutritional content of the diet influences distribution, population density, foraging strategy, body mass, survival, and reproduction (Stirling and Derocher 1990; Stringham 1990; Welch et al. 1997; Hilderbrand et al. 1999a, b; Rode and Robbins 2000; Robbins et al. 2007; Schwartz et al. 2010; McLellan 2011; Mowat et al. 2013). Although all bear species will consume human foods (i.e., garbage, agriculture, livestock) opportunistically, this entry focuses on the natural diets of bears.

## American Black Bear (*Ursus americanus*)

The diet of the American black bear varies by sex and age class. They also vary seasonally and geographically reflecting food availability. Across the majority of their range, plant matter is the primary diet item of American black bears with the remainder of their diet being composed

of animal matter, primarily insects (e.g., beetles (Coleoptera) and ants (Formicidae)), small mammals, and salmon (*Oncorhynchus* spp.) (Graber and White 1983; Inman and Pelton 2002; Fortin et al. 2006; Baldwin and Bender 2009; McLellan 2011). Hard (e.g., acorns (*Quercus* spp.), beechnuts (*Fagus* spp.), and hickory nuts (*Carya* spp.)) and soft mast (e.g., huckleberries (*Vaccinium* spp. and *Gaylussacia* spp.), blackberries (*Rubus* spp.), cranberries (*Oxycoccus* spp.), etc.) species are the highest caloric plant matter consumed by American black bears (Graber and White 1983; Inman and Pelton 2002; Baldwin and Bender 2009). Other plant matter consumed includes grasses (Poaceae) and herbaceous leaves and stems (Graber and White 1983; Inman and Pelton 2002; Baldwin and Bender 2009). Coastal black bears consume a higher level of meat, in the form of salmon, except where they are largely excluded from salmon use by sympatric brown bears (Jacoby et al. 1999; Belant et al. 2006; Fortin et al. 2006).

## Andean Bear (*Tremarctos ornatus*)

The diet of the Andean or spectacled bear is mostly herbivorous, although the importance of different plant species varies across their range in the Peruvian Andes, from the scrub desert to the tropical forest. The succulent hearts of bromeliads (Bromeliaceae) are the primary food of Andean bears when and where fruits are unavailable (Peyton 1980; Suarez 1988; Troya et al. 2004). Fruits are the second most important dietary item, including figs (*Ficus* spp.) and fruits of motilón (*Hyeronima macrocarpa*) (Peyton 1980; Troya et al. 2004). In the driest areas of their range, cacti (Cactaceae) are a food source and serves as an important source of water (Peyton 1980). Other plants commonly consumed include palm (Arecaceae) frond petioles, orchid (Orchidaceae) bulbs, the cortex of the pasallo tree (*Bombax discolor*), and shoots of bamboo (*Guadua* and *Chusquea* spp.) (Peyton 1980; Suarez 1988). In addition, insects, rodents (Rodentia), ungulates, birds, and honey are occasionally consumed (Peyton 1980; Suarez 1988; Troya et al. 2004).

### Asiatic Black Bear (*Ursus thibetanus*) and Sun Bear (*Helarctos malayanus*)

The Asiatic black bear and the sun bear are omnivores and have similar diets despite competition between the two species because of their overlapping habitats. Both species depend heavily on fruits and insects; however, it appears that neither species is able to meet their nutritional requirements on insects alone (Wong et al. 2002). The primary dietary items of both species are fleshy (e.g., figs, berries, and drupes) and hard fruits (e.g., acorns and stone pine seeds (*Pinus* spp.)), when and where available (Huygens and Hayashi 2001; Hwang et al. 2002; Wong et al. 2002; Fredriksson et al. 2006; Koike 2010; Steinmetz et al. 2013). Insects are the second most important dietary item to both species, with the sun bear consuming more insects than the Asiatic black bear, primarily ants, beetles, and termites (Wong et al. 2002; Augeri 2005; Fredriksson et al. 2006; Koike 2010; Steinmetz et al. 2013). Sun bears and Asiatic black bears also consume other plant matter, including leaves, stems, flowers, and legume pods, and on the rare occasion meat, including birds, eggs, reptiles, fish, and small vertebrates (Hwang et al. 2002; Wong et al. 2002; Augeri 2005; Fredriksson et al. 2006; Koike 2010; Steinmetz et al. 2013). In addition, sun bears consume honey and occasionally earthworms (*Lumbricus* spp.) and mushrooms (*Fungi*) (Augeri 2005). Across the range of both species, the dietary intake of fruits and insects depends on availability, spatially and temporally.

### Brown Bear (*Ursus arctos*)

As the most widespread species of bear, the omnivorous brown bear exhibits great diet plasticity, varying between seasons and years and between and within populations from coastal Alaska to the Gobi desert (Servheen 1983; LeFranc et al. 1987; Elgmork and Kaasa 1992; Jacoby et al. 1999; Schwartz et al. 2003; Batsaikhan et al. 2004; Mowat and Heard 2006; Vulla et al. 2009; Edwards et al. 2011; Gunther et al. 2014). The variation between and within

populations depends on social dynamic, learned behavior, individual preference, and population density (LeFranc et al. 1987; Gunther et al. 2014). The importance of meat and other high-caloric foods, such as hard mast and fleshy fruits, varies across their range.

In North America, the importance of meat to brown bears varies between coastal and interior bears and within different interior populations. In the Greater Yellowstone Ecosystem, grizzly bears consume  $\geq 266$  species within 200 genera from 4 kingdoms (Gunther et al. 2014). Salmon is the primary diet item in coastal brown bear populations (Jacoby et al. 1999; Schwartz et al. 2003; Belant et al. 2006; Fortin et al. 2006; Mowat and Heard 2006). Coastal brown bears also consume other meat (e.g., moose (*Alces alces*)), grasses, forbs, and berries (Jacoby et al. 1999; Schwartz et al. 2003; Belant et al. 2006; Fortin et al. 2006). Meat, primarily caribou (*Rangifer tarandus*), moose, bison (*Bison bison*), elk (*Cervus canadensis*), and small mammals, is the primary food item for some interior population, such as the Arctic, Greater Yellowstone, and Northern Continental Divide Ecosystems (Jacoby et al. 1999; Mowat and Heard 2006; Schwartz et al. 2014; Teisberg et al. 2015). Other dietary items include insects (e.g., ants, yellow jackets (Vespidae), and army cutworm moths (*Euxoa auxiliaris*)), grasses, forbs, berries, and seeds (e.g., whitebark pine (*P. albicaulis*)) (Jacoby et al. 1999; Schwartz et al. 2003, 2014; Gunther et al. 2014; Teisberg et al. 2015; Senset et al. 2016). There are some interior grizzly bear populations, such as the Cabinet-Yaak Ecosystem and interior British Columbia, where meat is less available and diets consist of berries (e.g., huckleberries, chokecherries (*Prunus* spp.), and crowberries (*Empetrum* spp.)), grasses, forbs (e.g., dandelions (*Taraxacum* spp.), fireweed (*Chamaenerion* spp.), and cow parsnip (*Heracleum* spp.)), roots, tubers, seeds, and fungi (LeFranc et al. 1987; Jacoby et al. 1999; Schwartz et al. 2003; Mowat and Heard 2006; McLellan 2011). These populations still consume, albeit in smaller quantities, ungulates (e.g., moose and deer (*Odocoileus* spp.)), insects (ants), and small mammals (e.g., voles (*Microtus* spp.) and

pocket gophers (Geomyidae spp.)) (LeFranc et al. 1987; Jacoby et al. 1999; Schwartz et al. 2003; McLellan 2011).

In European populations, there is a latitudinal gradient of meat consumption, with meat being a primary dietary component of brown bears in northern populations (i.e., Sweden and Norway), with decreasing dietary importance toward the southern populations (i.e., Italy and Greece) (Vulla et al. 2009; Niedziałkowska et al. 2019). Meat is consumed as prey and carcasses in the form of ungulates (e.g., moose, wild boar (*Sus scrofa*), and deer), insects, and small mammals (e.g., voles and ground squirrels (Sciuridae spp.)) (Clevenger et al. 1992; Elgmork and Kaasa 1992; Batsaikhan et al. 2004; Paralikidis et al. 2010; Štofik et al. 2013; Ciucci et al. 2014; Senset et al. 2016; Niedziałkowska et al. 2019). The diets of southern populations primarily consist of fleshy fruits (e.g., berries, rose hips (*Rosa* spp.), kiwi (*Actinidia* spp.), and plums (*Prunus* spp.)), hard mast (e.g., acorns and beechnuts), grasses, forbs (e.g., dandelions, firewood, and cow parsnip), roots, tubers, seeds, and fungi, with decreasing importance toward the northern populations (Clevenger et al. 1992; Elgmork and Kaasa 1992; Batsaikhan et al. 2004; Paralikidis et al. 2010; Štofik et al. 2013; Ciucci et al. 2014; Senset et al. 2016; Niedziałkowska et al. 2019).

Asian populations of brown bears do not show the same latitudinal gradient in meat consumption and are largely herbivorous. In northern Asia, the brown bear is more likely to rely on the Siberian pine (*P. sibirica*) than meat (Niedziałkowska et al. 2019). Other vegetation includes forbs (e.g., lagwort (*Petasites japonicus*), fennel (*Foeniculum* spp.), hogweed (*Heracleum* spp.), rushes (Juncaceae), grasses, acorns, and fruit (e.g., kiwi and berries) (Ohdachi and Aoi 1987; Sato et al. 2005; Sidorovich 2006; Niedziałkowska et al. 2019). Animal matter is a small part of their diet, mostly in the form of insects (e.g., beetles and ants), ungulates (e.g., deer, wild boar), small mammals (e.g., rodents), and crowfish (*Cambaroides japonicus*) (Ohdachi and Aoi 1987; Sato et al. 2005; Sidorovich 2006; Niedziałkowska et al. 2019). Along coastal Japan, brown bears also eat

seaweed, salmon, crab (*Paralithodes brevipes*), and shellfish (*Mollusca*) (Ohdachi and Aoi 1987).

### **Giant Panda Bear (*Ailuropoda melanoleuca*)**

The giant panda differs from the rest of the bear species in that it is an obligate herbivore with a diet comprised of approximately 95–99% bamboo (*Bashania* and *Fargesia* spp.) (Schaller et al. 1985; Reid and Jinchu 1991; Long et al. 2004). In contrast to other obligate herbivores, the giant panda retains the “simple stomach and short gastrointestinal tract” of the carnivore (Dierenfeld et al. 1982). To compensate, giant pandas consume large quantities of bamboo shoots and leaves (Hu et al. 1985), shift species of bamboo, age of the plant, and the plant part they consume to optimize nutrient intake (Hansen et al. 2010; Nie et al. 2015) and contain gut microflora to digest bamboo fibers (Zhang et al. 1988; Hirayama et al. 1989; Wei et al. 2007).

### **Polar Bear (*Ursus maritimus*)**

Polar bears are the only bear species that are almost exclusively carnivorous. The main prey item of polar bears is seals, primarily ringed seals (*Pusa hispida*) and to a lesser extent bearded (*Erignathus barbatus*), harp (*Pagophilus groenlandicus*), and hooded (*Cystophora cristata*) seals (Smith 1980; Ramsay and Hobson 1991; Derocher et al. 2002; Stirling 2002; Bentzen et al. 2007; Thiemann et al. 2008; Iverson et al. 2013). On occasion, polar bears will kill walruses (*Odobenus rosmarus*), narwhal (*Monodon monoceros*), and belugas (*Delphinapterus leucas*) (Killian and Stirling 1978; Smith 1985; Calvert and Stirling 1990; Smith and Sjare 1990; Thiemann et al. 2008). During long periods without sea ice, during which some polar bears are on land, they will consume coastal marine plants (e.g. algae), marine invertebrates, birds and eggs (e.g., snow geese), terrestrial plants (e.g., grasses, forbs, mosses (*Bryophyta*), and berries), mushrooms, and terrestrial animals (e.g., caribou, small

rodents) (Russell 1975; Ramsay and Hobson 1991; Derocher et al. 1993; Gormezano and Rockwell 2013; Iverson et al. 2013). However, polar bears are unlikely to meet their energetic requirements feeding on terrestrial foods in the long term (Stirling and Derocher 1990; Ramsay and Hobson 1991; Hobson et al. 2009; Stirling and Derocher 2012; Derocher et al. 2013). Although polar bears feed on whale carcasses where they are predictable due to subsistence harvesting by Native people or in unpredictable events, such as whale strandings, these carcasses are not a substitution for their natural prey of seals (Derocher et al. 2002; Miller et al. 2006; Bentzen et al. 2007). Some polar bears fast, or feed very little, while onshore in response to low food availability and the higher cost of locomotion on land (Latour 1981; Derocher and Stirling 1990; Ramsay and Hobson 1991).

### Sloth Bear (*Melursus ursinus*)

Although all bears, except polar bears, feed on insects, the sloth bear is the only one with special adaptations for feeding on insects. The sloth bear's diet is comprised of approximately 39–83% insects, primarily termites, ants, beetles, and other insects (Schaller 1967; Laurie and Seidensticker 1977; Joshi et al. 1997). The sloth bear has adapted to myrmecophagy with an elongated, bare snout; a long, flexible tongue; reduced incisors and post-canine teeth; and a gut microbiota similar to other myrmecophagous mammals (Seidensticker 1993; Sacco and Van Valkenburgh 2004; Delsuc et al. 2014). The majority of the rest of their diet, 14 to 61 percent, is comprised of fruit, including figs, dwarf date palm (*Phoenix roebelenii*), black plum (*Syzygium cumini*), and Chinese and sherbet berry (*Lycium* spp.) (Schaller 1967; Laurie and Seidensticker 1977; Joshi et al. 1997). They also consume flowers, grass, honey, and carrion (Laurie and Seidensticker 1977; Joshi et al. 1997).

### Conclusion

In this entry we described how diet varies by species, populations within species, and

seasonally. Most bears are generalist, omnivores that consume high-caloric foods when available, such as meat (e.g., ungulates and insects), hard mast fruits (e.g., acorns), and soft mast fruits (e.g., berries). Grasses, forbs, and other lower-caloric food items are consumed when high-caloric foods are limited and often meet the dietary needs of individuals because of their predictability spatially and temporally. A few species, polar and panda bears, are specialists and are primarily carnivorous and herbivorous, respectively. Understanding the dietary needs specific to each population of the eight bear species, and the subsequent habitat selection, is important for conservation and management. The diet of some species, such as the Alaskan brown bear, has been extensively study, whereas little research has been completed on other species, such as the Andean bear.

## Introduction

Life history traits are age- and state-specific characteristics that affect the life table of an organism. These traits are the result and the cause of variation within life cycles. Each of these life history traits is linked to the timing of events that make up the life of an animal and are investments in growth, reproduction, and survivorship of the individual or species (Gittleman 1986, 1993; Stearns 1976). Life history characteristics help to explain how an organism's anatomy, behavior, life span, reproductive development and behavior, and post-reproductive behavior are all influenced and shaped by natural selection and thus include various survival and reproductive strategies (Gittleman 1986, 1993). Therefore, these life history tactics can be thought of as a set of coadapted traits designed via natural selection to solve specific ecological problems. For example, reproductive strategies that lead to successful propagation may include things like seasonality of breeding,

litter size and frequency, age of weaning and independence of offspring, reproductive life span, and age of sexual maturity. Survival strategies encompass such characteristics as an organism's adaptations to inclement weather or conditions, defenses against predation, escape methods from altered or deleterious habitat, methods of moving through its environment, and specific foraging tactics (Garshelis 2004).

Ursidae, the second smallest family in the order Carnivora, includes eight extant bear species that can be found in a diverse range of habitats across North America, South America, Europe, and Asia. These species include the brown bear (*Ursus arctos*) found in Canada, the United States, Russia, Scandinavia, and Central Asia; the American black bear (*Ursus americanus*) found in the United States, Canada, and Mexico; the Asiatic black bear (*Ursus thibetanus*) of China and India; the polar bear (*Ursus maritimus*) of Russia, Scandinavia, Canada, and the United States; the giant panda (*Ailuropoda melanoleuca*) found in China; the spectacled bear (*Tremarctos ornatus*) of South America; the sloth bear (*Melursus ursinus*) of China, India, and Southern Asia; and the sun bear (*Helarctos malayanus*) of China, India, and Southeast Asia. Because of the low number of extant species within this family, less variation in life history traits might be expected in comparison to other carnivoran families (Garshelis 2004). However, because bears inhabit such a wide range of habitat types spanning from the tropics to the arctic, the potential for extensive variation among species exists. Whereas the polar bear is a tundra-dwelling species that traverses across the sea ice that covers the Arctic Sea during the winter months, the spectacled bear, sloth bear, sun bear, and Asiatic black bear all live in tropical forests, mountains, or lowland habitats. The American black bear, the giant panda, and the brown bear are all considered temperate species. However, individuals within a species may range across broad geographic areas and habitat types, thus allowing for variation in life history traits within a single species and not just among species.

Variation among bear species and within individual bear species can be explained by geography, habitat, and food habits (Gittleman 1986;

Garshelis 2004). It is difficult to make species-specific generalizations about the life history characteristics of bears, and there is likely far more variation than is presently acknowledged among the different species (Garshelis 2004). Some traits may not yet have been studied in all bear species, or certain traits may have not yet manifested in certain species because the conditions necessary for that trait's expression were not studied. Although several of these bear species have been studied extensively and much is known about their ecology and life histories, there are a few species that are still lacking research, and little is known about their life histories other than what can be gleaned from captive individuals.

### Reproductive Life History Traits

For most bear species, the breeding season occurs during the late spring and summer months, mainly between May and July. However, several species have breeding seasons that span outside this typical range. Polar bears engage in courtship behaviors and mating on the ice as early as April and May (Richardson 2014). Giant pandas have the earliest breeding season of all bear species, starting in March and typically ending in May (Zhu et al. 2001). Bear species reaching into the far northern latitudes like the American black bear and Asiatic black bear may continue to breed as late as August. Bears in warmer tropical climates, such as the sun bear, can mate at any point during the year, though females will only spend a few days to a week on breeding behaviors (Garshelis 2004). All bear species for which information about mating systems is available are considered promiscuous, meaning males and females frequently mate with more than one individual. Thus, because males will mate with multiple females in a given area, males do not assist in rearing cubs. Additionally, copulation is thought to occur numerous times in order to induce ovulation in females (Garshelis 2004).

After breeding, female bears utilize a strategy known as delayed implantation, or embryonic diapause, where the embryo does not immediately implant in the uterine lining after the egg has become fertilized. Instead, the embryo is

maintained in a state of dormancy where little to no development takes place, thus elongating the gestation period. Delayed implantation is thought to be a strategy to reduce risk during unfavorable environmental conditions, so that animals can time the birth of their offspring to line up with widely available food sources and more pleasant weather conditions, and to give offspring the highest chance of survival prior to birth (Garshelis 2004). In American black bears and brown bears, this embryonic diapause may last for several months, followed by approximately 2 months of gestation after implantation of the blastocyst in the uterine lining (Garshelis 2004).

Other than sun bears, which may breed and give birth to cubs at any point throughout the year, most other bear species will produce a litter between the months of November and February (Garshelis 2004). Giant pandas, however, may give birth between August and September. Whereas bears may give birth to litters ranging from one to six cubs, a litter will most commonly consist of one to three offspring, depending on food resources and maternal body condition. Because reproductive output is linked to maternal condition and maternal body condition varies over space and time, reproductive output also varies among and within bear species (Garshelis 2004; Robbins et al. 2012). American black bears and brown bears may have as many as four to six cubs in a single litter, if resources are plentiful. Giant pandas, in contrast, almost always give birth to twins, though only one cub typically survives (Zhu et al. 2001; Garshelis 2004). Sex ratios of bear cub litters born in the wild are very close to 50M:50F, although sample sizes for these studies are frequently small and deviation may not be detected accurately (Garshelis 2004).

Bear cubs of all species are born altricial, meaning they are born in an underdeveloped state (i.e., lightly furred or naked, and eyes closed) and completely reliant on their mothers to take care of them. In most species, including brown bears and American black bears, cubs are born during the winter and thus during the hibernation period (Robbins et al. 2012; Zedrosser 2006). Although not all bear species hibernate, almost all bear cubs are born in some sort of secluded

denning area such as a rock cave, a hollow tree, or an excavation in the dirt or snow (Garshelis 2004). On average, bear cubs are approximately 300 grams when born. Giant pandas show the most deviation from other bear species as birth weight of panda cubs is usually 90 to 130 grams, only about 1/800th the size of an adult female (Garshelis 2004; Peng et al. 2001; Zhu et al. 2001). Whereas other species of bears produce cubs that are lightly furred, pandas are the only species that produce naked, pink-colored cubs that develop fur and coloration patterns several weeks after birth (Peng et al. 2001).

Once born, cub growth rate and development among bear species vary. While Asiatic black bears are typically the first to open their eyes at 7 days and start walking at 4 days, they have one of the slowest growth rates among bear species (Yudin 1993). Asiatic black bear cubs born in January only reach a mass of approximately 2.5 kilograms by May (Yudin 1993). Giant pandas, due to extreme underdevelopment at birth, are just learning to crawl after the first 2 months (Peng et al. 2001). Conversely, most of the other bear species open their eyes and begin walking after the first month or so of life. In most cases, bear cubs remain in the denning area with their mothers for approximately 2 to 4 months, until they can emerge and walk about on their own (Garshelis 2004).

Although brown bears and American black bears will nurse throughout the duration of hibernation and into the spring and summer of their birth year, many other bear species continue to nurse for 2 years or more as a supplement to the cubs' other food sources. American black bear cubs, spectacled bear cubs, and sun bear cubs leave their mothers the earliest, becoming independent at 12–18 months. All remaining bear species stay with their mothers for the first 24–36 months of their lives. For this reason, many female bears will reproduce only every 3 to 4 years, rather than in a yearly cycle (Garshelis 2004). Females without cubs will enter estrus and mate when possible.

For many bears, peak reproductive age is between 4 and 20 years. Only three bear species reach sexual maturity at 3 years of age: sun bears,

sloth bears, and Asiatic black bears. All other bears attain sexual maturity at 4 years or later, with females typically maturing earlier than males. In polar bears and brown bears especially, males will breed later than most females for the first time because males need to gain enough size and mass to compete with more experienced, older male bears for breeding rights. Thus, male polar bears do not reach sexual maturity until 6 years of age and may not breed until 8 to 10 years of age. Because of these long time spans between birth and maturation, maturation and breeding, and one successful reproduction to the next, bear species are thought to have low birth rates (Garshelis 2004). Most bears are considered to be reproductively active until their early 20s, when they may start to experience senescence (Garshelis 2004).

### Survival Life History Traits

Adult bears can vary greatly in size, depending on species, sex, location, habitat, and food availability. Sun bears are the smallest of the bear species, often between 120 and 150 centimeters long and weighing only 27 to 80 kilograms even when full grown (Wong 2002). Spectacled bears, sloth bears, and Asiatic and American black bears are considered medium-sized bear species as they are typically larger than sun bears but still significantly smaller than the largest species. Polar bears are the largest bear species with the most massive of adult males measuring up to 3 meters long, 160 centimeters tall at the shoulder, and weighing up to 700 kilograms (Richardson 2014; Tartu et al. 2016). Brown bears and giant pandas are also large-bodied bear species like the polar bear. In all bear species, sexual dimorphism results in adult males often being larger than adult females (Richardson 2014).

While having to fuel a large body can often be stressful if food resources are scarce, a large body size is still beneficial in other ways. Because of their bulk, bears are not likely to be predated upon by any other animal. In most cases, bear mortality is caused by another bear, a human, old age, or lack of food. In fact, bear survival strategies and

life history traits commonly revolve around food sources and how to reach them (Garshelis 2004). Having a large body enables bears to move through their environment with relative ease, so that they can locate and move to seasonally available food sources (Garshelis 2004). Many bear species make large seasonal movements and have vast home ranges that they move through during certain times of the year. For example, polar bears travel on the Arctic sea ice during the winter months to hunt and gain significant amounts of fat, in order to survive the summer months on land without access to typical food sources. Brown bears frequently move to higher elevations to den for hibernation but then move down the elevation gradient after emergence to have access to berry crops and salmon spawning streams. Home range size and movement through the home range are almost entirely dependent on food availability and distribution within the environment (Swihart et al. 1988). When food is more abundant and more widely available in the environment, the home range tends to shrink as less area is needed to effectively gather food.

Male bears will typically establish larger territories than female bears, as they cover greater distances in search of mates during the breeding season. In fact, male territories frequently overlap home ranges of multiple females as a way of keeping track of potential mates (Wielgus and Bunnell 1994). However, intraspecific avoidance of males by females has been documented in five of the eight bear species. Females of several bear species specifically avoid areas that males are frequent once cubs have been born to avoid potential infanticide. Males ready to breed will often attack and kill cubs in an attempt to bring a female bear back into estrus (Wielgus and Bunnell 1994; Zedrosser 2006).

Despite these rather large home ranges that expand and contract with food availability and distribution, most bear species are rarely territorial. Home ranges within a species frequently overlap, though this also seems to vary with food availability and bear density (Garshelis 2004). Even with this overlap, bears tend to be mostly solitary in nature due to their large body size and large food requirements often barely met

with dispersed and/or nonnutritive food sources (Garshelis 2004). However, there are instances of bears displaying social behaviors outside of family groups and male-female interaction during the breeding season. Brown bears in Alaska frequently gather to feed on the same salmon streams, and polar bears and brown bears in Alaska have been observed feeding on whale carcasses and at dumps together. In these circumstances, bears will compete for the best feeding positions. Social hierarchies are established usually with the largest males in the prime spots, and younger bears and females relegated to the lower-quality feeding spots.

### Special Adaptations

With abundant food sources being restricted by dominant bears and main food sources changing seasonally, it is important that bears maintain a sort of dietary flexibility. Regardless of environment type (i.e., tropical or temperate), food availability varies widely by year, season, elevation, and habitat. In response to this constantly changing availability and distribution, bears are mainly opportunistic generalist omnivores, meaning they eat a wide variety of things. Bear diets are chiefly vegetation and plant material including roots, tubers, flowers, fruits, nuts, berries, grasses, and forbs but may also contain carrion, ungulates, fish, birds, eggs, insects, and smaller mammals (Rode and Robbins 2000).

Not all bear species follow this pattern of dietary flexibility, however. For example, polar bears have evolved to be almost exclusively carnivorous, feasting mainly on ringed seals (*Phoca hispida*) and eating only vegetative material, birds, eggs, and whale carcasses when forced ashore in the summer months after the sea ice melts (Richardson 2014; Tartu et al. 2016). Giant pandas, in contrast, have evolved to be almost exclusively herbivorous, in that their diet is restricted almost completely to bamboo. The panda's thumb is a modified sesamoid bone that helps to maintain a firm grip on bamboo shoots while eating, and powerful jaw muscles support a bite force strong enough to break through bamboo

shoots (Wei et al. 2015; Zhu et al. 2001). Pandas rarely eat other grasses, tubers, birds, or rodents, but a typical diet shift is from one species of bamboo to another. Another deviation, though not quite as extreme, is the sloth bear. The sloth bear is still considered omnivorous and opportunistic, but members of this species have a specially adapted lower lip and palate used to feed on insects and highly developed sickle-shaped claws for digging in termite mounds (Joshi et al. 1997). Depending on the time of year, sloth bears can shift diets from predominantly ants and termites to predominantly fruit and honey (Joshi et al. 1997).

When food is limited or disappears from the environment entirely, as is common in northern latitudes during the winter months, it becomes difficult for bears to maintain regular metabolisms and activity patterns without intaking food. Therefore, three of the eight bear species that range throughout these northern latitudes undergo a prolonged period of fasting and inactivity known as hibernation. American black bears, brown bears, and some Asiatic black bears in the colder, more northern portions of their range will hibernate. None of these species are obligate hibernators, however, meaning that hibernation does not need to occur if food is still seasonably available. American and Asiatic black bears in the southern portions of their range do not typically hibernate. During hibernation, the metabolism drops to 25% of basal rates, the body temperature lowers by several degrees centigrade, and heart rate decreases from 50–60 beats per minute to about 8–10 beats per minute (Hellgren 1998). Bears will not eat, drink, or defecate during hibernation. Instead, the bear survives by slowing utilizing the massive fat stores it accumulated during the summer and fall preceding hibernation (Hellgren 1998). Bears can lose 20–40% of their body mass by the end of hibernation but do not lose the use or strength of their muscles or bones (Hellgren 1998). Hibernation serves as an adaptation to surviving inclement weather conditions and periods without access to food.

Most bear species have specialized in the ability to climb trees, allowing them more access to three-dimensional space and potential food sources within their environments (Garshelis

2004). American black bears can frequently be found in trees, especially cubs waiting for their mother to return from foraging. Sun bears and spectacled bears are considered the most arboreal of the bear species and are known for their climbing abilities and the propensity to build tree nests for resting (Brown and Rumiz 1989; Wong 2002). However, not all bear species spend such large proportions of their time in trees. Polar bears, a tundra species, live in habitats that are mostly treeless, and their great body size would prevent them from being effective at tree climbing. Instead, brown bears and polar bears rely mainly on their body size and aggressive behaviors to ward off dangerous advances from humans or other animals (Garshelis 2004).

In general, bears have keen hearing and olfactory senses. Many bear species are able to smell and locate food from quite a distance away. For example, polar bears are thought to be able to detect food from 1.6 kilometers away, even if it is buried under a meter of snow (Rosing 1996). Additionally, many bear species are adapted to be strong swimmers. American black bears and brown bears are formidable swimmers, but polar bears have been known to regularly swim distances of over 48 kilometers at a time in search of stable sea ice, mates, and ringed seals (Pagano et al. 2012). Polar bears are also especially adapted for the cold temperatures of their Arctic habitat. They have large feet covered in papillae (i.e., tiny projections), built for walking across ice and snow and for propelling them through the water. Their long claws are designed for digging into the ice, and their bodies are insulated with adipose tissue to keep them warm.

## Senescence and Death

Bears are typically long-lived species, though cub mortality and adult mortality due to unnatural causes are not uncommon. Brown bears, polar bears, and American black bears frequently live into their 20s or 30s in the wild, and all eight species of bears have lived to at least 30 years in captivity (Garshelis 2004). There is limited information that suggests that bears may experience

declines in reproductive rates with old age, but most bear species continue to produce cubs into their 20s (Garshelis 2004). Research suggests that reproductive senescence could potentially follow a decrease in body mass or body condition later in life for many animals (Derocher and Stirling 1994; Richardson 2014). Thus, it is thought that bears that are unable to accumulate appropriate fat stores for reproduction may be unable to ovulate, conceive, or raise surviving cubs due to the influence of maternal body condition on these processes (Derocher and Stirling 1994; Richardson 2014). However, senescence in bears and its impact on other life history traits have not yet been investigated rigorously.

## Definition

Movement used by members of the family Ursidae to traverse their environment.

All bears belong to the family Ursidae. There are only eight recognized species of living bears, most belonging to the genus *Ursus*. Despite their limited taxonomic diversity, they have a near global range and can be found on all major land-masses except Antarctica, Africa, and Australia (Fig. 1). Members of the family come in various forms and sizes and range in body mass from the 68 kg sun bear (*Helarctos malayanus*) to the 700 kg polar bear (*Ursus maritimus*). Despite the range in body size and anatomy, all bears live fairly solitary lives with large home ranges. The need for these sizeable habitats requires bears to be highly adaptable and flexible in terms of diet and locomotor behavior. Bears range in diet from bamboo specialists to the largest land carnivores. In terms of locomotor modes, some species are highly arboreal while others utilize mixed aquatic and frozen tundra landscapes (Nowak 1999). This article discusses some of the general aspects of **bear locomotion**, while briefly touching on some of the more specialized locomotor behaviors observed in the family.

**Bear Locomotion, Fig. 1** Map demonstrating the current range of extant ursid species

**Bear Gaits and General Locomotor Behaviors**

Bears’ walking gaits consist of slow speed lateral-sequence lateral-couplet footfall patterns (Fig. 2). A lateral-sequence gait is one in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb). Commonly, during walking gaits, the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hindlimbs are traveling together, this is referred to as a lateral couplet; when the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal couplet. Very rarely do the limbs move together in perfect synchrony. Lateral-sequence lateral-couplet footfall patterns tend to be present in long-legged terrestrial animals and are assumed to be the best mechanism in preventing interlimb interference. However, this footfall pattern is thought to be inherently unstable because a majority (~66%) of the stride is spent as a unilateral bipod (i.e., only two ipsilateral limbs in contact with the support), which tends to roll the body side-to-side throughout the stride. This instability is argued to be negligible for long-legged animals (Granatosky 2018; Hildebrand 1976).

**Bear Locomotion, Fig. 2** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in ursids ( $n = 4$  species)

As locomotor speed increases, bears tend to change gait type. The gallop is the preferred means of locomotion when traveling at speeds more than  $4 \text{ m s}^{-1}$ . At intermediate speeds ( $2\text{--}3 \text{ m s}^{-1}$ ), bears deviate from the usual mammalian pace or trot, and instead utilize a running walk, which is a footfall sequence consistent with

their normal pattern of walking, but with decreased overlap between the feet. The trot and the pace require forelimbs and hindlimbs of equal length, with a straight short back; bears are characterized as having a relatively long, sloping back and this may limit their use of these gaits. One of the benefits of the running walk over a trot or a pace is the limited vertical fluctuation in the center of mass, as well as the ability to maintain contact with the ground with at least one foot throughout the stride. This suggests the apparent lack of a trot by grizzly bears may have implications for energetics as well. A lack of spring-like behavior in the bears' wrists may also be a reason why they prefer a running walk gait. A trot is more efficient for animals that store elastic energy in their tendons. Due to the shorter overlap between steps in a running walk, it is less affected by the need for elastic energy storage (Shine et al. 2015).

As with most nonprimate mammals, the forelimbs of bears tend to support the majority of their body weight (approximately 54–60%) (Granatosky et al. 2018). At walking speeds, the limb loading forces seen in the hindlimb have a characteristic M-shape pattern, which is possibly due to limb stiffness (Shine et al. 2015). This pattern is not seen in the forelimbs and is likely due to differences in impulses and weight distribution. The hindlimbs also tend to have the greatest rate of force development except at fast locomotor speeds. In terms of fore-aft forces, the forelimbs tend to be net breaking across all speeds. The propulsive impulses of both the forelimbs and hindlimbs are very similar. Bears differ from other large mammals in having substantially higher forelimb and hindlimb mediolateral forces. Such ground reaction force patterns may be attributable to the lumbering and splayed postures of the limbs (Shine et al. 2015).

### Plantigrade Locomotion

Foot postures are referred to as plantigrade when the complete length of the foot, involving the podials and metapodials, is positioned on the ground. This foot posture is observed in both bears and humans (Cunningham et al. 2010;

Pagano et al. 2018). Some hypothesize that plantigrady infers energetic benefits as the larger contact area minimizes directional change of the center of mass trajectory, which in turn lessens mechanical energy loss (Cunningham et al. 2010). Pagano et al. (2018) tested this hypothesis in bears by collecting mass-specific energetic costs of locomotion in grizzly (*Ursus arctos*) and polar (*Ursus maritimus*) bears. At routine walking speeds, they observed that polar bears and grizzly bears exhibited similar costs of locomotion and gait kinematics. Minimum cost of transport while walking in both species was comparable to predictions for similarly sized quadrupedal mammals, but these costs doubled at higher speeds. Similar to humans, bears appear to exhibit a greater economy while moving at slow speeds. Despite walking costs that were similar to those of other quadrupedal mammals, Pagano et al. (2018) found that both polar bears and grizzly bears have postural costs that are more than double predictions based on other quadrupedal mammals. The increased postural cost in both bears may in part be a result of their plantigrade posture as more erect limb postures (e.g., digitigrade and unguligrade) are known to have lower muscle mass and greater effective mechanical advantage (Biewener 1989; Reilly et al. 2007). Increased costs of running associated with plantigrade locomotion may also be attributable to the heel that absorbs energy once the stride begins. This eventually restricts storage and rehabilitation of elastic strain energy, mainly in the extensor muscles of the ankles.

### Arboreal Locomotion

Arboreal movement remains an understudied aspect of the locomotor repertoire of bears. However, not all bear species are equally proficient. The Malayan sun bear (*Helarctos malayanus*) is largely arboreal and is known as the best tree climber within the Ursidae. The sun bear is characterized by strongly curved, pointed claws and large paws with naked soles, which make them well adapted for climbing trees. Additionally, this species is capable of supinating the ankle,

allowing the hindfeet to “grip” the substrate rather than relying on claws or branches. In comparison, the larger brown bear shows little propensity for arboreal locomotion. These species are unable to “grasp” with the hindlimbs and instead keep the feet in a highly dorsiflexed position during vertical ascent (Fig. 3). Sasaki et al. (2005) demonstrated that these differences in relative climbing abilities have distinct consequences on the anatomy of the hindlimb. Specifically, they observed that the tarsal joint and foot of the sun bear and giant panda are more flexed and supinated than the polar bear and brown bear. Additionally, the tendon of the *m. tibialis cranialis*, a dorsiflexor and supinator of the foot, is shorter in the Malayan sun bear and the giant panda compared to other species. The combination of both traits allows the foot of arboreal bear species to be dynamically fixed and stable to external forces while positioned in a supinated posture.

The black bear (*Ursus americanus*) is also quite adept at arboreal locomotion (Bull et al. 2000) and will quickly ascend into trees or other high places when feeling threatened. Often, bear–human interactions result in black bears refusing to leave trees. Such instances often require wildlife professionals to intervene and safely remove the bear from the tree (Wolfe

et al. 2008) and relocate it to an area away from human interference.

## Swimming

All North American bear species (i.e., black bears, brown bears, and polar bears) are all capable of swimming. Bears will take to the water for purposes of fishing or travel. In the water bears can reach swimming speeds upwards of 2.7 m/s. Swimming is most important for polar bears as they move between sea ice patches. Pagano et al. (2012) reported that the duration and distance of long-distance swimming ranged 0.7–9.7 days and 53.7–687.1 km in polar bear. They demonstrate that adult female polar bears and their cubs are capable of swimming long distances during periods when extensive areas of open water are present. However, long-distance swimming appears to have higher energetic demands than moving over sea ice.

Griffen (2018) demonstrated that mean metabolic rate for a swimming polar bear to be  $2.75 \text{ ml O}_2 \text{ g}^{-1} \text{ h}^{-1}$ . When compared at the same movement rate, the cost of transport for swimming was estimated to be approximately  $5 \times$  that of walking. These findings demonstrate that increasing

**Bear Locomotion, Fig. 3** Arboreal capabilities of the Malayan sun bear (*Helarctos malayanus*; left), black bear (*Ursus americanus*; middle), and grizzly bear (*Ursus*

*arctos*; right). Note the supinated versus dorsiflexed position of the ankle in the highly arboreal Malayan sun bear versus black and grizzly bears

frequency and duration of long-distance swims in polar bears is energetically stressful. Energetic and thermodynamic costs of long swims may be further exacerbated by recent declines in body condition that have been documented due to climate warming.

### Captive Pacing Behavior

Species held captive in zoo like settings are often recognized for having particular behavioral abnormalities. Abnormal behavior in captive animals can include stereotypic behaviors – highly repetitive, invariant, functionless behavior, such as repetitive pacing, swaying, head-bobbing, bar-biting, over-grooming, or excessive licking. These behaviors can result from the frustration of natural behavior patterns, impaired brain function, or repeated attempts to deal with some problem (Swaigood and Shepherdson 2005). For bears held captive, their daily activities include exploration and foraging but the bulk of it consists of pacing (40–60%). Pacing behavior is continuous walking back and forth or in a circle, following the same path. Signs of regular pacing include definite paths worn in the ground. Observational studies have explored pacing in depth and have confirmed a stereotypic pattern of pacing present in certain bear species and not others. The black bear, for example, shows a classic and stereotypic pacing behavior in contrast to sloth bears. The black bear paces up to 8 hours/day with increased rates before and after feeding time. Cless et al. (2015) proposed a quantitative definition of pacing based on a reduction of locomotor variability compared to other “directed locomotor tasks” in polar bears. Such a finding indicates that pacing may constitute a similar invariant repetitive behavior similar to patients with autism. However, Granatosky et al. (2020) note that locomotor rhythmicity is a normal component of bird and mammal locomotion independent of pacing behaviors. The factors that predispose bears to pacing in zoos may be linked to large home range size, large daily travel distance, or large body size (Mason and Clubb 2004).

### Conclusion

As a group, the bears represent some of the largest living land carnivores. While they are limited in taxonomic diversity, they occupy a large geographic range. The quadrupedal gaits of bears are consistent, both metabolically and spatiotemporally, with other similarly sized mammals at slow speeds, but vary considerably when speed increases. Specifically, bears use running walks that are associated with increased costs of transport instead of trotting or pacing gaits. Limb loading for bears is distinct compared to other mammals due to relatively high mediolateral forces. These odd gait features may be attributable to plantigrade foot postures present across all bear species. Beyond terrestrial locomotion, some bear species are quite proficient at arboreal movement. The propensity to locomote in the trees varies considerably across the living taxa and is largely driven by body size (i.e., smaller species are more arboreal) and the ability to supinate the ankle joint. As a consequence of either large home range size, large daily travel distance, or large body size, bears are especially prone to pacing behaviors in zoos. Research to curb such behavior is active and ongoing.

Comparative Medicine, The University of  
Nebraska Medical Center, Omaha, NE, USA

## Synonyms

Ursid husbandry; Wild ursid management

## Definition

A review of the use of cognitive measures to improve the care and management of captive members of the family *Ursidae*, as well as the use of behavioral data to design mitigations for human-bear interactions in the wild.

## Introduction

Bears are large but intelligent terrestrial carnivores capable of complex spatial reasoning

tasks, such as tool use. This, combined with their size and aggressive behavior, makes them difficult to manage in both wild and captive settings – as they often interact with humans negatively. They are common culprits of depredation, property damage, and threats to human safety. In captivity, their size and complex cognitive requirements provide adequate cognitive and physical enrichment in order to prevent the development of stereotypical behavior and promote species-typical behavior. However, through understanding natural bear behavior and cognition (see the “► [Bear Cognition](#)” chapter of this encyclopedia for a review), managers are able to develop new and innovative interventions for wild and captive bears, to enhance their welfare as well as mitigate human-wildlife interactions.

## Managing Bears in the Wild

Efforts aimed at promoting wild carnivore conservation hinge on an ability to prevent and mitigate negative human-wildlife interactions. This requires a focus on aversive conditioning, the use of repellents and deterrents, controlling exposure to attractants, an understanding of species differences in threat perception, and knowledge regarding the general behavioral ecology of the target species.

Attempts to utilize classical conditioning to intervene in cases of livestock depredation by creating taste aversion to farmed animals and produce have yielded mixed results. These efforts have focused on bears, as well as wolves (*Canis lupus*) and coyotes (*Canis latrans*), and have featured the use of emetic chemical compounds (e.g., lithium chloride, cupric sulfate, or alpha-naphthylourea) combined with targeted bait items aimed at reducing the animals’ desire to consume this particular item again in the future (Smith et al. 2000). This approach has been demonstrated to be effective in reducing black bear depredation on beehives (Colvin 1975; Polson 1983), as well as in mitigating the raiding of campsites to obtain human food items by habituated wild black bears (Ternent and Garshelis 1999). Still, negative results have also been reported in similar contexts

(Smith et al. 2000); thus, further research into the cognitive processes involved in the selection and acquisition of prey items may be necessary to properly apply this mitigation technique effectively.

The principles of classical conditioning can be further applied to wild bear management through simply creating an association between a negative stimulus and humans and human settlements. This approach has also produced mixed results in nuisance grizzly bears in the Greater Yellowstone Ecosystem (GYE). Here, considerable work has been conducted to evaluate the methods of avoiding human-bear conflict in developed areas such as campsites, farms/ranches, and cities. In an attempt to create an association between pain and anthropogenic bear attractants, nuisance bears already possessing radio collars were baited with attractants. As the animals approached the attractant, they were fired upon using a Thumper Gun using bear-deterrent flash bullets as well as rubber bullet shot from a 12-gauge shotgun. This unconditioned pain stimulus was then paired with recordings from two non-native bird species (California quail and the ladder-backed woodpecker). The purpose of this approach was to create an association between the painful shot and the noise. Thus, in future encounters, researchers would simply play the sound stimuli in order to deter the bears from approaching developed areas. While this approach was effective for some nuisance bears, animals with compromised dentition, and those known to be long habituated to humans, did not alter their behavior in order to avoid humans and developed areas (Gillin et al. 1994). Radio-collared black and grizzly bears in Alaska exhibited aversive behavior in association with humans and human settlements after exposure to aversive stimuli such as plastic slugs and cracker shells. These methods cannot occur in a vacuum, however, and require human behavior change as well. Thus, public education programs including the promotion of bear-resistant food containers to control exposure to reinforcing stimuli and also temporary site closures due to increased bear activity are necessary for the effective mitigation of human-bear interactions in the wild (Schirokauer and Boyd 1998).

## Managing Bears in Captivity

In captivity, it is critical that a species' natural behavior is considered when designing enrichment and exhibits in order to reduce stereotypical behaviors (e.g., repetitive behaviors such as pacing, as well as more serious self-injurious behaviors) and promote optimal physiological and psychological welfare, exhibited by an increase in species-typical behaviors (e.g., digging, exploring the habitat, etc.). Clubb and Mason (2003, 2007) argue that bears, as wide-ranging carnivores, are particularly vulnerable to the exhibition of stereotypical behaviors, requiring both cognitive enrichment and species-specific enclosure improvements to promote optimal psychological welfare. Naturalistic enclosures that include soft substrate (such as dirt or sand) benefit bears as these materials allow for resident animals to engage in species-typical behaviors such as digging (O'Grady et al. 1990). This allows animal care staff to facilitate species-typical behaviors by introducing novel enrichment in the form of burying food and other enrichment items. When considering the design of naturalistic enclosures, it is critical to consider what constitutes *naturalistic behavior* for each species of ursid. For example, polar bears (*Ursus maritimus*) appear to benefit from flat enclosures, rather than the rocky or uneven habitats that benefit grizzly bears (*Ursus arctos*; Van Keulen-Kromhout 1978). Enclosures that provide a view extending beyond the animals' enclosure itself are associated with a reduction in stereotypical behaviors such as pacing (Shepherdson et al. 2013). Further modifications to enclosures to encourage naturalistic foraging behaviors such as pitfall feeders and log piles are useful in encouraging species-typical behaviors (Law and Reid 2010). Exposure to environmental enrichment is likewise critical in providing optimal welfare outcomes for bears living in human care. Common approaches to environmental enrichment for bears include object-based enrichment designed to encourage natural foraging behaviors such as honey logs, underground food pipes, wobble tree feeders (Veeraselvam et al. 2013), and live fish. Other enrichment such as scent trails has been demonstrated to be effective in stimulating species-typical exploratory and foraging behaviors in various bear species (Law and Reid 2010).

While it is important to keep the cognitive capabilities of bears in mind while designing both enclosures and enrichment, it is also useful in evaluating environmental enrichment protocols. For example, Keen et al. (2014) demonstrated that, through building upon existing knowledge regarding quantity discrimination in bears (e.g., Vonk and Beran 2012), cognitive bias tasks can be successfully employed in order to assess welfare in captive grizzlies. Still, this assessment found no effect of enrichment manipulation. Additional work with one black bear revealed that the bear responded optimistically in general; however, this study did not evaluate the effects of enrichment specifically (McGuire et al. 2017). Ross (2006) found that choice and control over enrichment were directly tied to positive welfare outcomes (i.e., an increase in species-typical behaviors and reduction in stereotypies). Additionally, physiological measures such as fecal glucocorticoid metabolites (FGM) have been found to be strongly linked to stereotypical behaviors in bears (Shepherdson et al. 2013).

There are many who argue that, in addition to this naturalistic approach to environmental enrichment for captive bears, artificial cognitive enrichment should also be considered as a viable approach to improving captive bear welfare. Specifically, training through operant conditioning challenges the animals cognitively in novel ways. Training captive animals to voluntarily participate in regular veterinary procedures (i.e., blood draws, examinations, etc.) as well as daily husbandry tasks (i.e., stationing in a particular place to allow caretakers the opportunity close a gate, etc.) has been shown to reduce behavioral and physiological indicators of stress in marine mammals (see Clark (2013) for a review). In bears, participation in such training – as well as training associated with their participation in cognitive testing (i.e., the use of a touchpad) – has been demonstrated to be enriching (Perdue 2016).

## Conclusion

As zoological institutions become more involved in the long-term conservation of large carnivores such as bears, it is even more critical that new and

innovative behavioral interventions be instituted to ensure the quality of the captive environment. In addition to managing captive populations, our understanding of ursid behavioral ecology, cognition, and problem-solving capabilities further enhances our ability to coexist with and conserve these apex predators in the wild.

## Introduction

The family Ursidae comprises eight extant species, generally classified into three subfamilies:

Ursinae (polar bear *Ursus maritimus*, brown bear *Ursus arctos*, American black bear *Ursus americanus*, Asiatic black bear *Ursus thibetanus*, sloth bear *Melursus ursinus*, and sun bear *Helarctos malayanus*), Ailuropodinae (giant panda *Ailuropoda melanoleuca*), and Tremarctinae (Andean bear *Tremarctos ornatus*) (Wagner 2010). Bears evolved about 20–25 million years before present (McLellan and Reiner 1994). Of the extant species, the giant panda diverged 12–20 million years ago, followed by the Andean bear about 7–13 million years ago, whereas the six species in the Ursinae diverged during the last 5 million years (Kumar et al. 2017). Bears attained a wide geographical distribution, mostly in the northern hemisphere (Kumar et al. 2017).

Morphologically and taxonomically, bears possess the distinguishing traits of Carnivora but, with the exception of the polar bear, are not obligate carnivores and often have diets comprised predominantly of plant matter. The generalist omnivore strategy that most bear species evolved with allows them to successfully occupy a broad range of habitats (Robbins et al. 2004). However, feeding on plant material with the typical carnivore digestive tract means relatively inefficient digestion. Complex hydrocarbonates

cannot be dissolved if not thoroughly chewed by flat crunching teeth and fermented properly in a complex stomach and long intestines. Bears compensate for these inefficiencies by consuming large quantities of food and selecting more easily digestible plants or plant parts, such as fruits. Many partly digested seeds remain viable for germination, thus making bears excellent seed dispersers (Koike et al. 2011).

General Morphology

The Ursidae family represents the largest terrestrial carnivores, although body mass ranges substantially from the largest polar bears to the smallest sun bears (Table 1). Bears have a robust body with a short tail and short but powerful limbs. All bears are quadrupedal plantigrades with five nonretractable claws. The head is large and has an arctoid shape with small eyes and rounded, erect ears. Bears have prehensile lips and tongue; the tongue is particularly long (20–25 cm) in sun bears and aids in the consumption of honey and insects. The coat consists of long guard hair and underfur of variable density depending on species and season. Sun bears do not have underfur, whereas underfur in sloth bears

is generally lacking or light, an adaptation to climatic conditions of their distributions. Bears are skillful in running, jumping, swimming, standing on hind legs, climbing, digging, and tearing.

## Coat

Although several bear species were named based on their coat color, substantial variations exist within each species. Brown bears have mostly light to dark brown fur, but the legs and shoulder hump can be almost black, including light-colored tips of hair that give these bears a “grizzled” look and contributed to the common name of grizzly bear used in interior portions of their range in North America. A small percentage of brown bears have fully black coats (Fig. 1). Young bears frequently have white patches, typically in the form of a chevron on the chest and neck. These patches become smaller with age and usually disappear fully, but some bears keep them their entire lives. Of all bear species, color morphs of American black bears (Fig. 2) are most geographically defined. They are uniform black in much of eastern North America, but different shades of brown are common in western regions and particularly the southwestern USA. Some populations on the Pacific coast of British Columbia, Canada, have many completely white individuals (“Kermode”

black bears), whereas a gray color morph occurs in southeastern Alaska. Because coat color is an inherited trait, different color morphs can be observed in a single litter of offspring. Polar bears are also called white bears because of the white appearance of their fur, but polar bear hair is free of pigment with a transparent, hollow core that scatters and reflects visible light. Some individuals may appear yellow or even light brown due to oils in their fur from prey they consume. The skin of polar bears is black. The unique and contrasting black and white fur of the giant panda has become one of the most recognizable symbols of wildlife conservation worldwide. They have a thick, woolly coat with black limbs, ears, and band across the shoulder and oblong-shaped, black eye patches. The remaining four species are all predominantly black, but their fur characteristics vary. Sun bears have the shortest fur of any bear species, whereas sloth bears have the longest fur, sometimes up to 20 cm, particularly around the neck, shoulders, and back, which likely facilitates cubs in climbing and riding on the back of their mother (Fig. 3). Almost all Asiatic black bears, sun bears, and sloth bears have a cream-colored crescent shape on the chest. This shape gave rise to the names “sun” bear (Fig. 4) and, for the Asiatic black bear, “moon” bear. These shapes and patterns vary and have been used to identify unique individuals in field studies (Ngoprasert et al. 2012). Andean bears have rough

black fur and unique, highly variable patterns of cream-colored fur around the eyes, which led to the common name spectacled bear. These patches of light-colored fur often extend down to the throat and chest and are sufficiently unique to identify individual bears.

## Body Shape and Skeletal Structure

Body mass varies greatly among species, within species, among different sex and age classes, seasons, and geographic areas. The sun bear is the smallest species, with adult body mass ranging from 30 to 80 kg, whereas body mass of adult male polar bears and brown bears can be ten times greater (Table 1). Although polar bears have the largest overall average size of all bear species, some individual brown bears in highly productive habitats can reach a body mass comparable to the largest polar bears. Sexual dimorphism occurs in all bears and can be particularly pronounced in the larger species, with males sometimes reaching double the body mass of females. Female bears typically reach their maximum skeletal size and body mass soon after sexual maturity, when they start investing in reproduction and rearing offspring, whereas male bears continue to grow and reach maximum structural body size years later, gaining competitive advantage for breeding and reproductive success (Bartareau et al. 2011). Body mass can vary by season, which is most prominent during fall hyperphagia among bears in temperate climates, when they consume copious amounts of food in preparation for hibernation and reach peak seasonal body mass (Kojola and Laitala 2001; Swenson et al. 2007). Habitat productivity strongly influences bear diets and, in turn, affects body mass and size. For example, all morphological measurements for both sexes were different in a study of four brown bear populations in Alaska, USA, with access to salmon resources as a key determining factor (Hilderbrand et al. 2018). Additionally, morphological measures within populations exhibited twofold differences for females and three- to fourfold differences for males. These differences suggest substantial plasticity in life history strategies, allowing brown

bears to adapt to changes within and across a variety of ecosystems (Kingsley et al. 1988; Hilderbrand et al. 2018).

Bears have a robust skeletal structure, with relatively short limbs and heavy bones and large scapula and pelvis to support their body mass. The forelimbs are strong and are used in various activities, ranging from digging for foraging or den construction to killing prey and interactions with other bears. Bears are quadrupedal with large, plantigrade feet, which likely enhances support of their large body mass and provides balance when they stand on their hind feet, which they frequently do to obtain olfactory or visual cues from their surroundings (Fig. 5).

The front paws of bears are sufficiently dexterous to aid in foraging for fruits, leaves, and insects. This dexterity is enhanced in the giant panda with an enlarged radial sesamoid bone that acts as a pseudo thumb for grasping bamboo stems. The digital and plantar foot pads range from nearly naked in sloth bears and sun bears to extensive hair separation in polar bears, providing traction on snow and ice. In sloth bears, the digital pads are fused. Bears have nonretractable claws that they use for climbing, digging, and tearing. Front claws are larger than hind claws. Claw size and shape are characteristic morphological features among bears, revealing key differences in their ecology. Curved claws benefit bears that often climb trees to forage, rest, or den, including sun bears (Fig. 6), Andean bears, and American and Asiatic black bears, whereas long, elongated claws are important tools for digging roots or ripping (brown bear) (Fig. 7), or excavating termites (sloth bear). Polar bear claws combine these features and are thick, curved, and sharp to catch and hold large prey and provide traction on ice.

## Locomotor System

With their body mass distributed toward the hind feet, walking locomotion is in the form of a lumbering gait. Bears can reach speeds as high as 55 km/h for short periods of time, but the energetics of their plantigrade posture dictate a greater

**Bear Morphology,****Fig. 5** Bear skeleton.

Bears have plantigrade locomotion and heavy skeletal structure to support their large body mass. They have powerful forelimbs and large feet to support a wide variety of activities. Their skull is massive and accommodates large and strong chewing muscles. Illustration is of an American black bear specimen from the Pratt Museum, Homer, Alaska, USA. (Courtesy © L. Post)

**Bear Morphology,**

**Fig. 6** Sun bears have long, sharp claws and large, robust canine teeth, which aid in opening up tropical hardwood trees to access bees and other insects, larvae, and honey. (Courtesy © L. M. Chiew – Bornean Sun Bear Conservation Centre)

economy while moving at relatively slow speeds. For example, the average locomotor speed of female polar bears over 10-min intervals on sea ice averaged 3.4 km/h (Pagano et al. 2018). Muscles of the bear body have an intensive activity of enzymes of aerobic and anaerobic metabolism that may help support the wide-ranging movements typical of bears; ATP-ase points to the high contraction capacity of muscle fibers (Kozarić et al. 1989).

The sacral vertebrae are fully fused in adult bears and firmly connected to pelvic bones. The short tail has no function in locomotion. The pelvis and femur are connected with the largest

muscles of the body, some of which extend to the knee. The whole system from the caudal portion of the backbone to the tibia is compacted, which assists in strong and enduring pacing and galloping. The fibula is small and of minor importance. Tarsal, metatarsal, and phalangeal bones support a large sole and relatively short hind claws. The scapulohumeral joint is shallow and the clavicle is missing. However, shoulder muscles are large and allow a wide range of motion.

A supratrochlear foramen in the humerus of brown bears can be observed only in some young individuals, indicating common ancestry with the Felidae but also early evolutionary

### Bear Morphology,

**Fig. 7** Claws of the front (top) and hind (bottom) feet of a brown bear. Claw size and shape are characteristic morphological features among bears, revealing key differences in their ecology. (F. T. van Manen – US Geological Survey)

separation, and now occurs only as a sporadic atavistic trait (Gužvica et al. 1995). The radius and ulna are not connected where they articulate proximally with the humerus and distally with the carpal bones and are crossed so the paw faces the ground, as is typical for a quadrupedal animal. This means that the proximal ulna is medial to the radius, whereas the distal ulna is on the lateral side (Adams and Crabtree 2012). Hence, the elbow joint allows a large angle of flexion and extension but also supination and pronation. Carpal, metacarpal, and phalangeal bones are packed with joints that give strength and stability for walking while providing the dexterity described previously, which is aided by curved or elongated claws.

Four bear species are arboreal or semiarboreal (sun bear, Andean bear, Asiatic black bear, American black bear) and whereas giant pandas spend most of their time on the ground, they are excellent climbers. Common to these species, curved claws facilitate climbing and are particularly well developed in sun bears, the most arboreal bear species. Several adaptations in the hind limbs aid tree climbing. For example, studies on the sun bear and giant panda showed that their hind limbs have a well-developed fleshy portion of the musculus tibialis cranialis that reaches the distal end of the tibia and is attached to the ossa metatarsalia via a short tendon (Sasaki et al. 2005). Additionally, the

musculus popliteus inserts near the distal end of the tibia. Combined, these adaptations allow stable dorsiflexion and supination of the foot and efficient pronation of the crus by leverage (Sasaki et al. 2005).

### Skull and Dentition

The arctoid shape of the head is supported by a massive and distinctive skull. Male skulls have a pronounced external sagittal crest (crista sagittalis externa) and are larger than female skulls (Farkas et al. 2009). The skull of bear species has diagnostic morphological features (including brown bears vs. cave bears; Gužvica et al. 1996), but distinct differences can exist even among populations of the same species. For example, measurable differences in skull morphology have been reported among brown bear populations (Fig. 8) (Sladek 1991; Colangelo et al. 2012). The brain case is “squeezed” by spatial temporal fossa (fossa temporalis) to accommodate large and strong chewing muscles. The space for muscles is bridged by a markedly wide zygomatic arch. In addition to the large surface of temporal bones, the most dorsal portions of the temporalis muscles have their origin on the external sagittal crest, which is most pronounced in adult males. On the mandible, musculus temporalis attaches to an extended and

large coronoid process. Strong masseter muscles originate at the zygomatic arch with insertion on tuberosity and outer surface of the mandibular ramus, and, aided by pterygoid muscles, they together exert enormous bite force (Christiansen and Wroe 2007). The typical extended nose accommodates spatial nasal conchae covered by epithelium with millions of olfactory cells, giving the bear an extraordinary sense of smell. The eyes are located in relatively small fossa orbicularis and are pointed forward. With such positioning of eyes, bears have a relatively narrow angle of vision but better three-dimensional sight, similar to primates. The maxilla and mandible host sets of very specialized, strong teeth (Table 2). They each hold 6 (3 + 3) relatively small incisors, placed and shaped to efficiently procure smaller-sized food

items and to scratch edible surface tissue from bones. The two pairs of large canines facilitate various aspects of food consumption (e.g., kill and hold down large prey, ripping trees or logs) but also serve as a formidable weapon in intra- and interspecific interactions. In the closed mouth, they fit closely together, paired from the upper and lower jaw. Posterior to the canines are two to four small, premolar teeth. The first three premolars are vestigial remains of atavistic jaws and serve no function in chewing food. The second and third premolars are small and often do not form or erupt, or are lost, leaving a diastema between the canines and functional cheek teeth. Premolar teeth are used by researchers and managers to age bears based on cementum annuli analyses (Matson et al. 1993). Carnassials are

the modified fourth upper premolar and the first lower molar paired to occlude in a shearing manner. Bears have a flattened and more blunt carnassial pair than felid or canid species. This trait reflects the bear's diet, as the flattened carnassials are effective both for slicing meat and grinding vegetation. The two upper and three lower molars are bunodont and are evidentiary that a large proportion of the diet of bears consists of plant matter. Although molar surfaces are quite flattened, they are distinctly different from molars found in true herbivores.

## Digestive Tract

The gastrointestinal tract of bears is typical of Carnivora, with a monogastric stomach and short, undifferentiated intestines. Food can move through the digestive tract in as little as 6–8 h, sufficient for digestion of sugars, starches, fats, and proteins (Pritchard and Robbins 1990). However, because bears lack a cecum or other specialized gastrointestinal areas, cellulose digestion is poor. As a result, bears consume large quantities of food and seek out the most nutritious and abundant foods in generally omnivorous diets. The polar bear and giant panda are exceptions and represent the extremes of an extraordinary range of diets within the Ursidae. Polar bears are obligate carnivores and have evolved as apex

predators of the northern Arctic sea ice, with ringed seals as their chief prey (Durner and Atwood 2017). Because prey availability is low, polar bear stomachs can expand to hold as much as 20% of their body mass. In sharp contrast, giant pandas are specialized herbivores, with approximately 99% of their diet consisting of bamboo species. However, digestion of fibrous plant matter in bamboo is limited by the carnivorous gastrointestinal tract, and recent studies showed that giant pandas do not possess the specialized gut microbiome typical of herbivores that assist in the digestion of cellulose and hemicellulose (Guo et al. 2018). Giant pandas may compensate for these limitations through increased food intake.

## Other Organ Systems

### Reproductive

Ovaries produce eggs in Graaf follicles during the mating season, but ovulation is typically postcoital (Fig. 9). Fertilized eggs develop to the blastocyst stage when they reach the uterus, which has two fully divided horns (uterus bicornis). In the horns of the uterus, one to four (exceptionally five or six) embryos spend up to 6 months in a dormant stage called embryonic diapause or delayed implantation, a reproductive specialization that occurs in approximately 100 mammalian species of 7 different orders (Renfree and Shaw 2000).

**Bear Morphology, Fig. 9** (a) Cortex of the brown bear ovary containing multiple follicles; Bar: 500  $\mu\text{m}$  (b) tertiary follicle in the cortex of the ovary; Bar: 1000  $\mu\text{m}$ .

**Bear Morphology,**

**Fig. 10** Bears have a multi-lobed (reniculate) kidney with increased surface area for removing toxins from the body more efficiently compared with a non-lobed kidney. Specimen is of a brown bear. (Courtesy © S. Reljić)

B

The proposed evolutionary significance of delayed implantation is that it uncouples the timing of breeding from parturition so they both occur during environmental conditions favorable for reproductive success. A consequence of this strategy is that newborn cubs of all bear species are very small (~0.5% of maternal body mass) and altricial, with closed eyes and short hair, fully depending on nourishment in the form of lactation and care from their mother. Thus, pregnant females of all bear species, including non-hibernating bears, give birth in a protective, maternal den and remain there until the cubs are 2–3 months of age.

In the tubules of testicles (vesiculæ seminales) of adult males, active sperm can be found during all seasons. The penis is supported by a penis bone (baculum) as in all carnivores and cetaceans.

**Urinary**

The bear kidney is multi-lobed (reniculate kidney) as is also found in pinnipeds and cetaceans (Fig. 10). Bovines are the only other terrestrial mammals whose kidneys do not lose their fetal lobulation. Kidneys with this morphology have increased surface area for removing toxins from the body more efficiently compared with a non-lobed kidney. This may be particularly important for bears during hibernation, when they demonstrate a remarkable ability to recycle urea nitrogen (Stenvinkel et al. 2013).

**Respiratory and Circulatory**

Similar to other organic systems in bears, the organs for breathing and blood circulation are massively developed and satisfy a broad range of needs, from short bursts of strenuous activities such as chasing prey, to climbing trees or walking hundreds of kilometers in search of food or other resources, to extended periods of fasting and hibernation. Respiration and heart rates in hibernating bears decrease much more than non-hibernators can achieve, although not as low as typically observed in smaller hibernating mammals (Hellgren 1998).

## Introduction

Some bears occupy incredibly large home ranges, particularly in low-productivity habitat. It is thought that, for some species of bear, home range size is primarily influenced by the availability of food (Koehler and Pierce 2003). Bears are highly mobile and can travel immense distances, which is critical in species that often rely upon ephemeral food sources. Some species like the sloth bear (*Melursus ursinus*) have comparatively small home ranges, possibly due to the prevalence of concentrated, relatively ubiquitous food sources like insects and fruits in their diet. More omnivorous bears such as brown bears (*Ursus arctos*) and American black bears (*Ursus americanus*) tend to have larger home ranges in less productive habitat like arctic tundra and smaller home ranges in highly productive areas, like coastal regions with salmon streams. Polar bears (*Ursus maritimus*) inhabit some of the largest home ranges of any ursid. As the most purely carnivorous bear, they depend largely upon irregularly distributed seals for food and must move across shifting ice to locate their prey and find mates. Polar bears sometimes travel long distances to return to land to create maternity dens or to fast during sea ice breakup when open water makes terrestrial fasting more energetically efficient than continuing to hunt. Regardless of home range size, navigation is essential in locating food sources and mates. Due to the inherent difficulty of studying wide-ranging large carnivores and the special challenges relating to the study of animal navigation, little is known about how bears navigate large and sometimes featureless landscapes.

## Polar Bear Navigation

Navigation-related questions are particularly intriguing with respect to marine animals that lack immobile external landmarks to guide them. Polar bears live in a dynamic high-latitude environment of sea ice, which may consist of more stable, landfast ice or drifting pack ice characterized by continual changes in extent and configuration as ice sheets break, refreeze, and collide

(Ferguson et al. 2000). Therefore, more pelagic polar bears (i.e., bears that primarily live on sea ice and rarely spend time on land) like those inhabiting the Barents Sea lack fixed navigational landmarks. Barents Sea polar bears perform seasonal migrations but do not alter their large-scale movements to negate displacement caused by the drifting sea ice, likely because local prey availability is more important than maintaining a home range in a certain absolute location (Mauritzen et al. 2003). However, some studies have shown that polar bears on pack ice can compensate for sea ice drift (Larsen et al. 1983) and maintain site fidelity for activities that are typically terrestrial, like denning. This implies that bears are able to sense their position on moving ice and compensate accordingly. Note that most polar bear movement data is from collared females: collars do not stay in place on males because the circumference of their necks is greater than that of their heads (Pagano et al. 2012).

Unlike other bear species, polar bears regularly undertake long-distance pelagic swims. A study of 52 adult females in the southern Beaufort and Chukchi Seas showed that 38% of these bears swam long distances ranging from 53.7 to 687.1 km in length and lasting 0.7–9.7 days, often accompanied by dependent cubs. The average distance traveled was 154.2 km over a period of 3.4 days. These swims were point-to-point and often occurred near the September sea ice extent minimum as bears traveled from unstable, unconsolidated sea ice to land or to pack ice (Pagano et al. 2012). Polar bears' ability to use olfactory, visual, and auditory cues would be diminished during long swims. Additionally, their destinations may be so distant as to be beyond their sensory capabilities, suggesting the presence of other navigational mechanisms. However, navigational mechanisms like internal compasses or the use of magnetic fields have not been studied in ursids (Sahanatian 2015).

In many locations, polar bears travel to land during the summer when the sea ice extent is nearing its minimum. It is unknown how females locate their summering grounds. Female polar bears in Hudson Bay preferred to come ashore at familiar areas for the summer during ice breakup

rather than stay on the sea ice longer and return to land at an unfamiliar location. Because these bears hunt while on the ice but fast on land, by maintaining site fidelity, they cost themselves the opportunity to gain additional energy (Cherry et al. 2013). Polar bears typically display fidelity with respect to spring feeding areas and denning locations (Wiig et al. 2003). Female polar bears returning to hunting grounds with cubs-of-year followed a similar heading and remained parallel to other traveling family groups. These females did not take the shortest route to the ocean and did not follow landscape features like streams (Ramsay and Andriashek 1986). The linear travel of these family groups suggests that polar bears have exceptional navigational abilities.

Polar bears could be using olfaction to navigate. Sea ice deforms to create ridges that average 2 m in height and 12 m in length, making use of vision to locate prey challenging. Indeed, ringed seal behavior seems to indicate that bears use olfaction while hunting. Hauled-out ringed seals face downwind, which would allow them to sense bears approaching from upwind via olfaction and would allow them to see bears approaching from downwind. A 2-year study of 123 Hudson Bay polar bears fitted with GPS collars revealed that bears traveled crosswind when winds were slow ( $<36$  km/h) in the winter, which would be consistent with crosswind olfactory search for prey. Crosswind movement is optimal for detecting odors in steady winds or during large-scale searches (Togunov et al. 2017).

## Homing

Studies of homing tendencies can also illuminate navigational strategies. Many bear species have remarkable homing abilities that often stimulate attempts to translocate problem animals. Homing research conducted using translocated bears has shown that it is unlikely that ursids rely exclusively on landmarks to navigate. In a 1986 study, five American black bears (two adult females, one subadult female, and two yearling males) were radio-collared and monitored for at least a year to establish the boundaries of their

home range. Each bear was then captured, drugged, and transported up to 60 km from their home range; they were unconscious for some or all of the transportation period. Despite their novel surroundings, the two adult females traveled homeward quickly (one averaged 11.4 km/day). One female returned to her home range in 9 days; the other disappeared while on a direct course toward her home range, having traveled 43 km closer to home when she was last located. The adult bears moved at a steady pace homeward regardless of wind direction, so it is unlikely that they were solely dependent on receiving olfactory cues from their home range (Rogers 1986).

The younger bears did not home consistently. One male yearling did not return home, while the other yearling returned home in 1 week. The female subadult returned home after being translocated 25 km. She was then recaptured and transported 66 km (Rogers 1986), after which she did not return home. The mixed homing tendencies seen in these younger bears may be because bears leave their family groups and disperse as subadults. In American black bears and brown bears, male subadults are typically more likely to disperse and may travel farther away, whereas females may exhibit natal philopatry or disperse smaller distances (Larivière 2001; McLellan and Hovey 2001; Steyaert et al. 2012). This movement away from their mother's home range may be a way to avoid inbreeding (Steyaert et al. 2012).

A meta-analysis of 8 studies involving 77 translocated American black bears found that the 43 bears that did not return to their home range still exhibited a homeward orientation in their travel. This indicates that bears are not using random exploration or search patterns to return home. Moving bears very far ( $>120$  km) from their home range did not alter the proportion of bears that moved homeward, as might be expected if bears navigated using landmarks – hypothetically, bears would be less familiar with distant landmarks and would fail to navigate as well as bears released closer to their homes. However, bears translocated over 1400 km moved in random directions after release (Rogers 1987).

This suggests that American black bear navigation may depend upon local cues accessible only within shorter ranges. Some bear populations regularly, predictably make shorter-range movements: in some areas, bears travel long distances to take advantage of seasonally available ephemeral food sources like fruits and nuts (Noyce and Garshelis 2011), and select populations of bears migrate to denning areas. Studies of these seasonal shifts in bear movement could illuminate which cues are most important for successful navigation.

## Social Cues

One such study was conducted on an American black bear population in Minnesota. Eighty three female and 124 male bears were radio tracked from 1981 to 1990, with 64 bears of each sex being tracked for multiple years, in an attempt to determine how bears know when and where to migrate in the fall. These data indicated that it is unlikely that cubs learn migratory behaviors or routes from their mothers: migrations performed while cubs accompanied their mother did not influence whether the cubs later migrated as independent juveniles. Siblings behaved differently following family dissolution. Some siblings migrated, while some remained in their summer home ranges. In cases where multiple siblings migrated, in all but one instance, siblings traveled in different directions to different final destinations. Numerous males migrated to denning areas despite the fact that their mothers never migrated to den. Additionally, fall movements did not appear to be instinctive, as bears followed different routes to varying locations each year. Landscape features included wetlands and lakes. Bears traveled around lakes but directly through wetlands. It is possible that in more extreme landscapes, geographical formations could funnel bears into more distinct paths. Bears did not appear to use food gradients to navigate because highly productive foraging grounds were patchily distributed rather than present along a gradient (Noyce and Garshelis 2014). This study reinforced earlier research (Rogers 1986) showing

that bears were likely not reliant on long-distance olfactory indicators of ripening food sources, as their movements did not follow prevailing winds. Bears departed at different times and traveled in different directions, which would not be the case if wind-borne scents instigated their movements. The authors suggest that bears used social cues to determine their routes. In 1988 an anomalously large number of females (32) left their home ranges in late summer. During these migrations, 53% of these bears were located in association with a neighboring female bear that normally occupied a home range adjacent to the focal bear's range. Similarly, of 28 bears that were located while moving to a denning area near another collared bear, 24 were associated with a bear from a neighboring home range. Subadults and female bears often foraged, denned, and traveled in corridors away from adult males, while adult males used other areas. Most bears that were tracked since cubhood did not return to the areas where they had foraged with their mothers. Male bears may disproportionally influence population movement patterns, as their long-range travel as subadults may give them greater knowledge of distant food resources. Additionally, they may more directly influence the movements of other bears, as females and subadults often stay away from adult males to avoid conflict (Noyce and Garshelis 2014). Chemical communication via rub trees and other marked objects may influence subadult behavior; some bear species are capable of discerning at least age, sex, and reproductive status from scent cues alone (Rosell et al. 2011; White et al. 2002, 2004). Additional research is needed to concretely demonstrate the link between social cues, navigation, and large-scale movements.

## Working Memory

On a smaller scale, bears may rely upon working memory to locate active feeding sites or other resources. Captive adult giant pandas (*Ailuropoda melanoleuca*; eight males, nine females) were administered a spatial memory task between November 2009 and February

2010, when wild male pandas experience elevated testosterone and expand their ranges prior to the breeding season. Eight feeders were placed in a circle. Four were baited, but all feeders were scented with the food item, and feeders were structured such that there were no visual cues to indicate if the feeder was empty or full. Pandas were allowed to explore the feeders. The next day, all feeders were scented, but none contained food. All pandas were more likely to visit the previously baited feeders during the first four trials. In the remainder of the nine trials, male pandas were significantly more likely to visit previously baited feeders than were females. Males were less likely to revisit feeders that they had already checked during that session than females. The authors suggest that these results reflect the importance of working memory in male giant pandas during range expansion, which allows males to better track the locations of females and marking sites and thus potentially be more reproductively competitive (Perdue et al. 2011).

## Conclusion

Although many bear species routinely travel long distances and exhibit site fidelity, only a few species have well-characterized home ranges, dispersal tendencies, and long-range movement patterns throughout their range. Bear navigational mechanisms remain largely unknown. Ursids exhibit remarkable homing capabilities and may use social cues to determine movement patterns. Bears may follow olfactory cues to find prey, other bears, and to return to familiar sites from new locations, but because they seem to be able to navigate regardless of wind directionality, they are likely also using other navigational mechanisms like celestial or magnetic cues.

## Introduction

Bears evolved and diverged beginning in the late Oligocene and early Miocene, about 20–25 million years ago, attaining a wide geographical distribution range. The family Ursidae includes eight extant species, generally classified into three subfamilies: Ailuropodinae (giant panda *Ailuropoda melanoleuca*), Tremarctinae (Andean bear *Tremarctos ornatus*), and Ursinae (Malayan or sun bear *Helarctos malayanus*, sloth bear *Melursus ursinus*, American black bear *Ursus americanus*, brown bear *Ursus arctos*, polar bear *Ursus maritimus*, and Asiatic black bear *Ursus thibetanus*). Morphologically and taxonomically, they possess all the traits of carnivores but, with the exception of the polar bear, have diets

often comprised primarily of plant matter. Most of the current bear species evolved with a generalist omnivore strategy, which allows them to occupy a broad array of habitats (Robbins et al. 2004).

Diverse habitats and their physical characteristics create challenges that influenced the evolution of sensory structures in bears. Bears must detect meaningful cues and signals through complex and challenging environments. An extreme example of this is the semiaquatic habitat that creates a unique sensory challenges for polar bear, a terrestrial mammal living as a marine mammal, which is not aquatic in the sense of navigating or hunting underwater like pinnipeds yet must still sense and interpret stimuli in both water and on land (Togunov et al. 2017; Lone et al. 2018). Additionally, bears are solitary and non-territorial, and as such, they benefit from conveying multi-modal cues to expedite the breeding season, to recognize family and kin, and to avoid conspecifics. Available anatomical, histological, and behavioral evidence suggests that bears are somatosensory specialists, with an excellent olfaction (Togunov et al. 2017), color vision (Bacon and Burghardt 1976), good hearing (Nachtigall et al. 2007; Owen and Bowles 2011), and sense of taste accommodated by gustatory papillae of both herbivorous and carnivorous characteristics (Pastor et al. 2008; Pastor et al. 2011). Bears also possess neuroanatomical correlates for the sensations received by their extremities (e.g., Kamiya and Pirlot 1988). They have been shown to rely mostly on olfaction, audition, and vision, although the significance and relative quality of some modalities remains to be investigated. Along with these commonly recognized senses, bears may also receive and respond to one other type of sensory information: magnetic fields. Evidence suggests that at least two terrestrial carnivores may respond to magnetic fields, and the retinas of bears contain a light-sensitive pigment that may react to magnetic fields (Nießner et al. 2016). However, although some individual bears can navigate without using familiar physical landmarks, the ability of bears to detect magnetic fields has not been tested.

## Visual Perception (Vision)

Overall, the eyes of bears are broadly similar to that of most mammals. As in all mammals, the retinas of bears' eyes contain two general types of receptive cells: rods and cones. Rods are more sensitive to light than cones, which require strong light stimuli. Rods are used to perceive movement, while cones permit the perception of color. Humans and some but not all primates are trichromatic. That is, they possess three kinds of cone cells. It's been suggested that this type of color vision has evolved to help some primates find fruits. However, although several bear species forage heavily on fruits at least seasonally, no bears possess trichromatic vision: bears do not see color as we do (Peichl 2005).

New research methods have recently revealed more diversity in mammalian photoreceptors than was previously known. Genotyping the areas responsible for the five vertebrate photoreceptor opsins (proteins) has revealed two cone types in the retinas of most diurnal mammals, including bears, making them dichromatic. The relative abundance of the two cone types in bears has not been evaluated, but those two types of cones should permit discrimination of short wavelength hues (violet, blue) from long wavelength hues (green, yellow, orange, red), but not between different long wavelength hues (Peichl 2005). The visual conditions under which polar bears live are unique among bears: the polar bear's snow- and ice-covered habitat has little variation in color, but great variation in illumination depending on weather and season. In addition, polar bears are semiaquatic, and light travels through water differently than through air. Given these environmental factors, polar bears might be expected to have reduced color vision, or to lack color vision altogether, as do many marine mammals (Peichl 2005), including their most common prey (Levenson et al. 2006). However, behavioral testing of polar bears and analyses of their DNA indicate that their color vision is similar to that of other terrestrial dichromats, with peak responsiveness to both violet-blue and green (Levenson et al. 2006). There has been little other behavioral testing of bears'

ability to discriminate among colors, but giant pandas discriminate green, red, and blue from gray (Kelling et al. 2006), and American black bears discriminate blue and green from gray (Bacon and Burghardt 1976). It is believed the remaining bears have similar abilities.

The broad pattern in mammals is for vision to evolve in ways that enable the mammal's ecological niche (Peichl 2005). It's believed that bears use their visual abilities primarily in foraging and in communication with other bears. Due to the orientation of their eyes, bears have binocular vision, which narrows their field of view but enhances their depth perception. Like other carnivores and many other placental mammals, the eyes of bears contain a reflective layer, the tapetum lucidum, which improves their ability to see under low conditions. In the wild, several if not all bear species display shifts in activity patterns that reveal their ability to use either brightly lit or poorly lit conditions to optimize their foraging success or avoid other individuals of the same species or potentially hazardous individuals from another species, including humans. Bears are often active primarily during the day (diurnal) when humans are not present, and at least two species, the Andean bear and the sun bear, are quite arboreal, but unlike other some other diurnal arboreal mammals (e.g., tree squirrels), their retinas are not cone-heavy. Thus, a bear's eye functions well at low light levels but without high spatial and temporal acuity.

## Auditory Perception (Hearing)

### Sound Perception

Bears have well-developed external ears with moderately stiff pinnal flanges and are assumed to have good hearing across species. American black and brown bears appear to use auditory cues in salmon streams (Klinka and Reimchen 2002). Polar bears can hear well in air the relatively low frequencies of vocalization produced by seals, their prey (Owen et al. 2016). The behaviors used by bears to locate sound are described as erecting the ears while lifting the head, then visual scanning to follow the source

of sound, and sniffing if the sound is of other animals, especially potential prey (Nachtigall et al. 2007).

The anatomy of the auditory region provides important insights about the hearing capacity. Anatomical descriptions of the auditory region exist for some among extant ursid species (giant panda, Andean bear, sloth bear, American black bear, polar bear, and brown bear; Segall 1943), as well as for some extinct bears. Until now, the polar bear and giant panda remain the most studied bear species in terms of auditory perception, investigated using evoked potentials or behaviorally (go, no-go response protocols). The size of the mammalian hearing apparatus increases throughout the class Mammalia in modest proportions with increasing body size. The middle ear ossicles have to withstand the forces produced by the tympanic membrane vibrations. Thus a large mammal with a large tympanic membrane, such as a polar bear, needs massive middle ear ossicles, which in turn results in a decreased capability for the transmission of high-frequency sounds. Therefore, considering their size, polar bears were expected to have moderately good low-frequency hearing; Owen and Bowles (2011) showed in-air best hearing sensitivity between 8 and 14 kHz and its upper limit to be 10–20 kHz lower than that of the small terrestrial carnivores. A decline in functional hearing in polar bears was observed at 125 kHz. Earlier work by Nachtigall et al. (2007) noted good hearing sensitivity of polar bears within a range of 11.2–22.5 kHz: absolute thresholds lower than 27–30 dB. The frequency range of the polar bear's hearing is wider than in humans, and they can hear well the relatively low frequencies of vocalization produced by seals, in air. Polar bears' auditory adaptation for underwater hearing remains unknown. Giant pandas have functional hearing into the ultrasonic range, with best sensitivity at 12.5–14.0 kHz and the lower and upper limits at 0.10 and 70 kHz, respectively (Owen et al. 2016). Compared with the polar bear, the giant panda's hearing is similar, although more sensitive at and above the frequency of 16 kHz. Interestingly, the sensitivity of panda hearing is lower within the range of

cub vocalizations, making cubs potentially vulnerable to dampening and fitness-reducing effects of anthropogenic ambient noise. An awareness of the studies species' acute and relatively wide-frequency hearing, and vulnerability for acoustic signals to be masked by anthropogenic noise during sensitive life stages, should be applied in anthropogenic noise management, as noise may impact bears. In the light of the deleterious potential of noise, additional research on the high-frequency hearing of all bears is needed.

### Vocalizations in Bears

The ability of bears to produce sound is strengthened by the presence of epipharyngeal pouches, which are constant and unique features throughout the family Ursidae. The histological structure of the pouches strongly suggests its functional involvement in the respiratory system. Additionally, they can enlarge and retract in response to various states of air inflation, apparently important in ursid phonation (Weissengruber et al. 2001). Bears vocalize during agonistic interactions with conspecifics, for example, to both defend young and secure resources. The agonistic vocalizations include “huffing” (loud deep breathing), “snorting” (loud expelling air through mouth and nostrils), “gurgling” (low-pitched warbling, throaty rumble), and “loud growling.” There have also been other close range vocalizations (e.g., “chuffing”) described for some of the bear species, with suggested but untested functions of appeasement, reassurance, greeting, coaxing, and maintaining contact at close range, most frequently used by females with cubs, by males and females during courtship and mating, and by adults and juveniles during friendly close contacts. Giant pandas will also “bleat” and Andean bears will also “trill,” but other bear species appear not to use these vocalizations. “Humming” has been observed in all bears but the giant panda, sometimes by adult bears but largely restricted to cubs (Baotic et al. 2013; Peters et al. 2007). Cub vocalizations are mainly restricted to nursing and grooming contexts and consist of calls such as “chuffs,” “croaks,” “growls,” “grunts,” and “huffs,” as well as

“barks,” “cries,” “screams,” “squalls,” “squawks,” “squeals,” “whimpers,” “woofs,” and “yelps” emitted in distress situations, and “humming” to communicate well-being to the mother.

While relatively little is known about the importance of auditory cues in bear foraging or risk avoidance, compared with other modalities used, vocalizations and their role in intraspecific communication have been thoroughly researched in some bear species. The giant panda is the most studied species in those aspects, with quantitative descriptions of the acoustic structure of male and female bleats showing that they code for sex, age, and size that is important to receivers in reproductive contexts. Individuals perceive and attend to this information when assessing potential rivals and/or mates. Male and female giant pandas can then adjust their behavioral responses according to the age- and size-related information broadcasted by bleats (Charlton et al. 2012). Several previous studies have provided verbal descriptions of other bear vocalizations, but quantitative descriptions, based on the analysis of acoustic properties, are relatively rare (Pokrovskaya 2013; Baotic et al. 2013).

### Olfactory Perception (Olfaction)

Adult bears are solitary, which is associated with a greater reliance on olfaction for communication. Although behavioral data suggests that bears use olfaction in foraging, such data also suggests that the most important use of olfaction by bears is in communication with other bears. Olfaction has been most thoroughly studied in the brown bear, polar bear, and giant panda, but indirect behavioral evidence on olfaction has been collected in all bears.

Research on the morphology of olfaction assumes that the relative surface area or size of a physical structure is correlated with the importance of that structure. The nasal cavity of bears, like other mammals, includes a maze of thin bones covered by a thin layer of skin with numerous chemical receptors. These receptors convert airborne molecules into electric impulses that are transmitted to and processed by the bear's brain.

The predatory polar bear has a relatively large portion of its nasal cavity devoted to olfaction, compared to the American black bear, brown bear, and other more omnivorous carnivores. In bears, the relative size of the olfactory bulb, the brain area focused on olfaction, is larger than expected based on the trend seen in other carnivore species (Gittleman 1991), and the size of the bony plate dividing the nasal cavity from the olfactory bulb is larger than would be expected in the American black bear, the brown bear, and especially the polar bear (Bird et al. 2014). Thus, bears appear to rely more on olfaction than do most other carnivores. Airborne compounds stimulate nerve impulses not only in the nasal cavity but also in the vomeronasal organ (VNO), which humans do not possess. The VNO is located on the roof of the oral cavity, and in many mammals, it is important for the reception and processing of compounds involved in intraspecies communication. Only a little research has been done on the morphology and function of the VNO in bears, but the VNO of brown bears and Asiatic black bears is well developed and similar to that of doglike carnivores, except that some gland cells are perhaps uniquely developed in bears.

Olfaction requires the conversion of airborne molecules into nervous impulses. Little is known of this process in most bears, but various proteins which bind airborne molecules are distributed differently in the nasal cavity and in the VNO of brown bears than they are in other mammals. The other limited information available suggests that the molecular mechanisms of olfaction in bears are tuned to compounds linked to foraging and to communication among individual bears.

Bears commonly receive olfactory information from other bears through sniffing, in which airborne molecules are brought into the nasal cavity. Individual bears are known to sniff others' feces, urine, deposits on marked trees, and footprints. This behavior has been reported by male and female bears of all ages, but it is most often reported from adult males, especially during the mating season (Clapham et al. 2014). Another behavior, called flehmen, brings airborne molecules into contact with the VNO. Flehmen

involves raising the upper lip, closing the nostrils, and inhaling through the open mouth. Flehmen has been reported in all bears but sloth bears, which presumably perform it; flehmen is almost always performed by male bears, not females.

Bears use various diverse and complex behaviors to release compounds with olfactory information. These behaviors vary across species with individual age, sex, reproductive status, and perhaps dominance status and population density. Individual bears of several species are known to claw, bite, or rub their chest, neck, shoulders, head, back, or flanks on woody vegetation or surrogates that humans place in bear habitat (e.g., wooden power poles). In addition, American black bears, Andean bears, brown bears, and sloth bears are now known or strongly suspected to actively deposit molecules with their feet in a behavior called pede marking (Owen et al. 2014; Sergiel et al. 2017). Giant pandas may also deposit scents with their feet, but individual pandas more obviously communicate with others by depositing anogenital secretions as high as possible against vertical substrates by performing a handstand.

Giant pandas possess a well-developed anogenital gland which produces unique secretions, while other bears release secretions from less well-developed anogenital sacs (Rosell et al. 2010). The skin of the footpads and between the toes of brown bears and polar bears contains prominent glandular cells (Owen et al. 2014; Sergiel et al. 2017). Glandular cells on the backs of adult male brown bears produce an oily substance only just before and during the breeding season. It is unknown whether this is so in other bears.

Brown bear feet produce compounds that could differentiate males from females (Sergiel et al. 2017). Scents produced by giant pandas may vary among males and females and in various ways between the breeding and non-breeding season (Wilson et al. 2019). Variation of scents in giant panda urine and anogenital secretions may contain information about the sex, age, reproductive status, and perhaps even individual identity of the panda producing the odors (Zhou

et al. 2019). Similarly, anogenital secretions of brown bears contain enough variation to differentiate males from females (Rosell et al. 2010). The urine of female brown bears and female Andean bears releases airborne compounds that vary seasonally with levels of reproductive hormones.

Knowledge of what bears perceive through olfaction is incomplete. Giant pandas of both sexes and all ages can discriminate conspecific sex via the scent of urine (White et al. 2004). Similarly, subadult brown bears appear to differentiate between anogenital secretions of adult male and adult female brown bears (Jojola et al. 2012). Finally, male polar bears differentiate the sex and reproductive condition of other polar bears through their pedal scents (Owen et al. 2014).

Some researchers have explored the use of olfaction to repel American black bears, brown bears, and polar bears, with mixed success for ammonia and with the most consistent success for red pepper spray (Smith et al. 2008). Food-based scents have been used to attract Andean bears, American black bears, and brown bears for research and management purposes, but it's not well-known how the response to those attractants varies within and among bear populations and with the individual bear's past experiences. The compounds which bears use to learn about their environment and other bears must be readily airborne, but they must also persist over time. The life span of these compounds depends not only on molecular characteristics but also on environmental factors such as airflow and humidity. There has been a little theoretical and empirical research on how environmental factors affect olfaction by polar bears (Togunov et al. 2017), but those predictions might be dramatically different in the forested habitats in which most other bears live.

## Tactile Perception (Touch)

While the senses of vision, hearing, olfaction, and taste have their own organs, the sense of touch depends on sensory nerve endings distributed

over the entire body. There are sensory nerves connected to each hair follicle, pain and temperature receptors scattered throughout the skin, and motor nerves that innervate the erector pili muscles and glands. This rich innervation is crucial to sense the environment and react accordingly. The extent of innervation depends on the nature of the tissue, but mammalian skin and skin-related tissues are relatively highly innervated with apparent regional differences. Specialized skin cells (Merkel cells) involved in touch sensation reside in the epidermis, passing mechanical stimuli on to sensory neurons. In some mammals, including bears, they are concentrated in the paws and vibrissae (whiskers). Whiskers are specialized sensory structures relaying vibrotactile information from the environment to the central nervous system. Most mammals possess them, with location, numbers, and function varying across species. Many mammals use them for active discrimination of tactile cues (e.g., rodents, felids, and many pinnipeds), but in bears vibrissal movement is relatively passive, and the hair shafts of vibrissal follicle-sinus complexes are reduced in size, similar as in dogs and other canids (Marshall et al. 2006). Deeper in the skin there are corpuscular receptors, of which Meissner corpuscles (tactile corpuscles) respond to light touch and Pacinian corpuscles (lamellated corpuscles) respond to vibrations. These receptors tend to be concentrated in the most touch-sensitive body regions of mammals, such as fingers, palms, and paws.

Bears appear to be quite “manual” and use their paws for foraging and manipulating food, exploring, and marking. Both American black bears and brown bears were observed to use tactile (and acoustical) cues when shifting from visually oriented foraging during the day to foraging in the darkness while fishing for salmon in forest streams (Klinka and Reimchen 2002). In addition to foraging, tactile senses are relevant to various social behaviors, orientation, and navigation. In bears, relatively extensive touching and rubbing is observed during play and in maternal, sexual, and social contexts. Tactile contacts are also present during aggressive interactions.

## Gustation (Taste)

Bears’ sense of taste is thought to be primarily used in foraging. Although polar bears are primarily carnivorous, giant pandas are almost entirely herbivorous, and sloth bears are primarily insectivorous, the other four bear species are omnivorous with diets that vary among species, among populations, and even among individuals. Bears’ taste receptors are located within their mouths in small structures (papillae) with both herbivorous and carnivorous characteristics (Pastor et al. 2008, 2011). Research into the nutritional ecology of bears has improved our understanding of the complexity and function of foraging across bear species, but that research alone does not reveal the sensory cues by which bears select their diet. It’s thought that most mammals use different receptors to perceive five classes of taste: sweet, umami, bitter, salty, and sour. Selective foraging by bears can be very fine-scaled, which may reflect temporally variable chemical and nutritional characteristics of potential food items, which bears presumably detect through differences in flavor. Genetic analyses have suggested that, in general, as the diets of various mammals have changed, their sense of taste has also changed. However, it’s unclear that differences in diet among the different bear species are reflected by differences in their sense of taste. In addition, although some marine carnivores have lost the ability to taste sweet, bitter, and perhaps umami flavors, those functions have not yet been evaluated in the semi-marine bear, the polar bear. In experimental tests, Andean bears, known to eat at least 300 species of plants and 40 species of animals, have preferred foods containing sugars and some other sweeteners (Jiang et al. 2012).

Although incomplete, the most-developed research linking a bear’s sense of taste, foraging, and nutritional ecology has been conducted in the giant panda. Giant pandas only rarely eat meat, and it’s been suggested that they’ve lost the perception of umami (Zhao et al. 2010), which reflects amino acids in foods. Molecular and behavioral evidence indicates that giant pandas, similar to Andean bears, taste simple sugars and

prefer foods with them (Jiang et al. 2014). That preference may mediate the seasonal shifts in foraging preference among wild giant pandas for bamboo culm versus bamboo leaves, coinciding with seasonal shifts in the relative abundance of sugars and nondigestible fiber in those plant tissues (Knott et al. 2017). In addition to sweet flavors, bamboo also includes bitter-tasting compounds. Consistent with the potential for bitter flavors to be important cues for the giant panda, the giant panda possesses genes for bitter taste receptors that are not found in several carnivores that do not feed on bitter-tasting foods, including the polar bear (Shan et al. 2018); it is not known bears with more diverse diets perceive or respond to bitter flavors.

There have been attempts to use bears' sense of taste (e.g., reaction to capsaicin as in hot peppers) to repel them from potential sources of conflict with people and to teach them to avoid anthropogenic food sources. These attempts have not been consistently successful and have revealed complex interactions among sensory systems; although pepper spray may repel brown bears and polar bears when in an aerosol form, the non-aerosol form of that same mixture may attract bears, possibly through its flavor (Smith et al. 2008).

## Begging

Callen M. Inman

Department of Integrative Biology, University of Texas-Austin, Austin, TX, USA

## Synonyms

[Bleating](#); [Offspring solicitation behavior](#)

## Definition

Begging is a form of communication in which organisms solicit resources provided by other organisms. It almost always occurs when dependent young solicit resources from their parents and often involves multiple signals designed to induce parental provisioning.

## Introduction

Begging is a familiar behavior in birds and mammals. Begging in nestling birds has a striking visual component: nestlings stretch their necks upward towards the parent and widen their gapes (Jacob et al. 2011). Equally conspicuous are the acoustic signals of begging birds, which make high-frequency and repetitive sounds that subside once they are fed (Budden and Wright 2001). Placental mammals employ analogous “bleating” calls during the period of lactation, and

invertebrates such as burying beetles may wave their legs and touch parents in order to induce provisioning (Parker and Mock 1997; Smiseth and Parker 2008). Begging is present in amphibians: in several species of poison dart frogs, the larvae “beg” visually and vibrationally by approaching the mother, stiffening their tails, and moving their body from side so that their mother will deposit unfertilized eggs to feed them (Stynoski and Noble 2011).

Offspring begging occurs only in organisms in which parents provision resources for offspring and in which this provisioning is partially inducible by the offspring. A key implication of begging behavior is that offspring are not passive receptacles for parental nourishment, but that they are to some degree in control of the amount of parental investment they receive, as well as the distribution of resources among the offspring (Trivers 1974). The amount of provisioning can only be controlled by offspring in species in which provisioning is continuously supplied by parents, rather than as a fixed initial supply in the form of yolk (Furness et al. 2015). Begging is only present in species with a reliable degree of parental provisioning of offspring. In species in which young disperse far from the parents and only provision themselves, begging has not been selected for (Smiseth et al. 2003).

The definition of begging is almost always restricted to postnatal contexts. It has been proposed, however, that this definition should be expanded to include the prenatal environment. Trivers (1985) suggested that chemical messages sent from embryo to mother via the mammalian placenta could function similarly to postnatal auditory begging calls, and other researchers have classified hormonal signals sent from fetus to mother as begging signals (Kilner and Johnstone 1997). However, unlike begging calls, placental hormones do not show fluctuation in accordance with physiological changes and are instead likely to convey relatively invariant information such as “vigor” or “quality” (Haig 1996). In contrast, a prenatal begging signal could be emitted more strongly by an individual in good condition than by an individual in poor condition, but a given individual would not emit a hormonal signal at the same level of intensity regardless of

its hunger. Additionally, because the two genetically distinct individuals (mother and fetus) share the same physiological pathways, receptors in the maternal bloodstream that respond to hormonal signals cannot determine whether the hormone originated in mother or offspring. But in postnatal forms of resource solicitation, there is no ambiguity as to the source of a message: a mother bird easily differentiates between her own body's signals and those of her offspring.

The literature on begging is rich with theoretical models explaining how begging behavior might arise and be maintained under a specified set of conditions. Like most species-general behaviors and morphological traits, begging behavior warrants an evolutionary explanation. Two main perspectives on begging have developed over time in the literature: begging as a form of manipulation and begging as a form of honest signaling.

### Begging as a Form of Manipulation

Reviews of animal communication prior to the 1970s primarily assumed that animal signals were straightforward and informational, resulting in reduced ambiguity about the environment for the receiver (Cullen 1966). In the 1970s, however, verbal models of signaling began to consider the fact that signals evolve because they benefit the signaler, and so we should expect them to be manipulative and often dishonest (Krebs and Dawkins 1978). Researchers in the field of animal behavior increasingly realized that Hamilton's rule ( $rB > C$ ) specified not only the conditions under which an individual should behave selfishly towards a relative but also the evolutionary limits of selfish behavior (Hamilton 1964; Parker and Mock 1997). Thus, even within families, there would be a fitness "nonoverlapping zone," reflecting the different genetic interests of individuals. Trivers's central insight in his seminal paper "Parent offspring conflict" was that the genetic interests of parent and offspring differ; parent and offspring are expected to "disagree" over the length and amount of parental investment (Trivers 1974).

Since dependent offspring are generally incapable of *physically* overpowering their parents, Trivers reasoned, we should expect offspring to evolve ways of *psychologically* manipulating their parents into providing them with resources.

Parker and MacNair (1978) developed a series of models expanding on Trivers's insight, showing that alleles causing greater resource solicitation from offspring spread under conditions of both monogamy and promiscuity. If ignoring offspring solicitation signals incurs costs, the model expects offspring solicitation to push parental provisioning above the optimal amount for the parents, but below the optimal amount for offspring (Parker and MacNair 1979; Parker and Mock 1997). In these "pro rata" models, parents and offspring bargain over the level of investment, and offspring's bargaining power comes from the reduction in fitness caused by intense begging via metabolic, predation, or physical costs (Roulin 2000). According to some verbal models, offspring begging can conceivably "blackmail" parents into provisioning more than is optimal for them (Zahavi 1977). However, the pro rata models generally show that any "blackmailing" that evolves is generally unlikely to be evolutionarily stable, and only under very specific conditions does any party emerge as the "winner" of the conflict.

The evidence for the prediction that parent-offspring conflict results in deceptive signals on the part of offspring is scant in the literature, and only a few studies have examined interspecific variation in the honesty of begging. Trivers (1985) suggested that broods with lower relatedness between siblings would experience a higher degree of parent-offspring conflict. Lower relatedness between siblings would incentivize higher sibling competition and increase the disparity between optimal provisioning from the mother's perspective and optimal provisioning from the offspring's perspective. A comparative analysis of begging behavior across 60 bird species found that offspring begging was less honest in species where parents produce more broods and where parental divorce or death reduces between-brood relatedness (Caro et al. 2016). However, subsequent analysis demonstrated that this might be a

premature conclusion, as the two sets of half-siblings produced by divorced parents should have equal or higher inclusive fitness value to an individual offspring than a single set of full siblings. Thus, individuals in species with higher rates of parental divorce would not necessarily be incentivized to act more selfishly at the expense of their siblings. If begging signals are less honest in species with higher rates of parental divorce, it is not explained by kin selection (Bebbington and Kingma 2017).

Begging signals certainly demonstrate features that appear designed to capture the attention of parents (Kilner and Hinde 2008). In birds, solicitation behaviors consistently involve repeated calling of a single note and displaying of a red, yellow, or orange patch. Canary nestlings with artificially red-dened gapes receive preferential provisioning from parents (Kilner 1996). The brightly colored mouths of nestlings in many bird species are surrounded by an area that reflects ultraviolet light well, and nestling tree swallows have been found to make longer, louder calls across a wider frequency range when ambient noise increases (Hunt et al. 2003; Leonard and Horn 2005). Scramble competition models of begging assume that parents allocate food in proportion to the signal intensity of the offspring relative to the average of the brood as a whole (Royle et al. 2002; Dugas and Rosenthal 2010). In the scramble competition model, begging is not necessarily honest or dishonest. Rather, parents passively respond to the stimuli that are most salient to them, so that they are in a sense manipulated into allocating food in a certain way by their offspring. Selection on both parents and offspring may favor a stable begging communication system. It is unclear that easily noticeable and even flashy begging signals are necessarily manipulative.

Failing to pay attention to offspring signals may be costly to both parents and offspring, and instances of true offspring manipulation by begging are apparent in brood parasitic Horsfield's bronze-cuckoo chicks, which closely resemble the structure of Superb fairy-wren begging calls (Colombelli-Negrel et al. 2012). True offspring manipulation has also been observed in brood parasitic Horsfield's hawk-cuckoos which mimic

the yellow wing patches that simulate three begging chicks in the nest (Tanaka and Ueda 2005; Langmore et al. 2011). In the case of brood parasite manipulation, Trivers's theory of parent-offspring conflict need not be invoked. Honest signaling systems are always susceptible to invasion by deceptive mimics of other species that fool receivers' sensory systems. But manipulation has not yet been shown to be a general rule of begging communication systems, and host parents are expected to exert frequency-dependent selection against such manipulation due to the costs that they bear (Jamie and Kilner 2017).

According to Trivers, an individual offspring should maximize the amount of resources it receives relative to its siblings. On the other hand, parents are expected to maximize the number of offspring that survive. Under this asymmetry, parents should be selected to allocate resources equally to each of their offspring. And offspring should be selected to manipulate parents into giving them more than their fair share of resources. Parents should be selected, in turn, to resist offspring manipulation.

Honest begging models have called into question the idea that allocating resources to offspring equally to each of their offspring is optimal for the parents. Additionally, they call into question that begging signals by offspring are necessarily manipulative rather than informative. Rather than driving an endless tug-of-war between parent and offspring, parent-offspring conflict may instead result in an evolutionary "compromise" between both parties: an honest signaling system (Godfray 1995b; Kilner and Hinde 2008). The signal of need hypothesis and the signal of quality hypothesis are the two major functional explanations of honest begging.

## Models of Honest Begging

Early models showed that parent-offspring conflict could give rise to an evolutionarily stable equilibrium in which an offspring solicits resources in a way that reduces its fitness, and parental provisioning increases so as to prevent further expensive solicitation signaling (Stamps et al. 1978; Parker

1985). Godfray (1991) presented an alternative explanation for costly solicitation. He showed that the level of offspring solicitation can be an honest reflection of offspring need as long as solicitation is costly and the benefit of extra resources increases with need. Godfray's (1991) model helped to shift the landscape of begging models from ones that define the extent of parent-offspring conflict to those that predict its resolution (Godfray 1995b). Godfray expanded his model of an evolutionarily stable signaling system between offspring and parents by modeling the influence of within-brood relatedness, offspring condition, and the total amount of resources available for the brood (Godfray 1995a).

Godfray's model also offers a theoretical analysis of both intrabrood and interbrood competition. Intrabrood competition occurs when an individual demands resources at the expense of other brood members, and interbrood competition occurs when one brood demands resources at the expense of future broods. Godfray assumes that the parent provides a fixed amount of resources and that the young may differ in condition or state, which determines the degree to which they will benefit from an increased share of the resource. By honestly signaling their condition or state with begging calls, the young increase the efficiency with which the parent allocates resources. In theory, the higher the marginal benefit of extra resource is to an individual offspring, the more an offspring will be expected to invest into solicitation signaling. Whether signaling is a truly costly phenomenon is unclear. Two studies in birds have shown significant increases in metabolic rate resulting from increased begging, and one study in house sparrows has shown that begging behavior may compromise immunocompetence (Bachman and Chappell 1998; McCarty 1996; Moreno-Rueda 2010). However, these findings do not conclusively demonstrate that the metabolic or immunological costs of begging exceed the threshold needed to maintain honesty. There is some evidence that begging signals attract predators, but few empirically informed cost-benefit analyses of begging in relation to predation have been performed (Redondo and Castro 1992; Haskell 1994).

The assumption built into Godfray's model, that costs are associated with honesty, is not a necessity for offspring-parent signaling systems. Godfray's model also incorporated the idea that offspring begging may be influenced by the condition of siblings in the same brood. Thus, along with reflecting the state of the signaler (that signaler's condition or temporary hunger), it may also reflect the state of its surrounding siblings (Kilner and Johnstone 1997). For example, nestling barn owls may refrain from vocalization when a rival sibling is hungrier than they are, and they may escalate their own begging once that rival is fed by parents (Roulin et al. 2000). Additionally, begging intensity has been shown to decrease with brood size, as the inclusive fitness cost of gaining resources at the expense of one's siblings is higher when there are more of them (Cotton et al. 1996; Roulin et al. 2000). In the case of expressing information about their need and (in an indirect way) expressing information about the level of need of their siblings, offspring are assumed to be communicating information about their state that is otherwise cryptic to the parent (Godfray 1991). Many researchers have tried to identify correlates of hidden condition, such as body size or physical development. However, many of these cues are not cryptic and thus a begging signal would be redundant and of lower value if a parent could merely assess visible cues of condition to get the same information (Mock et al. 2011; Schwagmeyer and Mock 2008). Another problem with the "signal of need" literature is that overall condition, the "need" that Godfray's models refer to, and temporary hunger, are frequently confused. Food deprivation experiments have repeatedly demonstrated that the intensity of offspring solicitation signaling increases in response to hunger. But hunger is not clearly related to fitness, so in order to determine whether offspring solicitation intensity is truly a function of need, hunger and condition must be decoupled (Mock et al. 2011). The confusion between proximate-level wants and ultimate-level needs has likely contributed to the neglect of viable hypotheses explaining the evolution of begging other than "signal of need."

The second major honest signaling hypothesis explaining the evolution of begging is the signal of quality hypothesis. The signal of quality hypothesis makes the opposite prediction of the signal of need hypothesis: that better-condition signalers emit stronger signals because they can afford them. The model builds upon the handicap principle, the idea that a signal's honesty is maintained by the fact that it suggests something about the signaler's condition. If the signaler were in poorer condition, it would not be able to bear the costs of the signal (Zahavi 1975). Compared to the signal of need hypothesis, the signal of quality hypothesis has been largely neglected in the literature despite its theoretical and empirical plausibility (Grafen 1990; Weary and Fraser 1995; Saino et al. 2000). The adaptive value of responding to a begging signal that honestly advertises quality is obvious when it is considered from the perspective of the parent. That is, parents should be selected to put limited food resources where they will have the highest fitness returns.

Hypothetically, parents that respond to signals of need and allocate more resources towards offspring in poor condition may risk wasting their limited resources on offspring that will not have high fitness returns either way. On the other hand, if parents direct resources towards offspring in better condition, they may be able to increase their fitness returns, measured in the number of grandoffspring, to an even higher level. Though tests of the signal of quality hypothesis have been limited relative to tests of the signal of need hypothesis, SoQ may explain results in the begging literature more effectively than SoN. For instance, provisioning rate predicts fledgling size and recruitment as breeders in a house sparrow population (Schwagmeyer and Mock 2008). In house sparrows, parents are responsive to begging calls and posturing and allocate resources according to begging signal intensity. This relationship between eventual condition and provisioning rate would not arise if needier offspring invested more energy into signaling. And videotaped house sparrow parents skew allocations towards larger offspring (Mock et al. 2009). Additionally, when nestling house sparrow mouth flanges were painted to resemble nestlings in

good condition, parents shifted their feeding patterns to prefer them over nestmates (Dugas 2010). This suggests that some components of begging, particularly the brightly colored (and high UV-reflecting) mouthparts of young engaged in solicitation behavior, may be hard-to-fake cues to offspring condition rather than merely flashy signals designed to manipulate parents.

In a completely different taxon, earwigs, offspring nutritional condition is revealed by variation in a chemical signal, cuticular hydrocarbons. If cuticular hydrocarbons are extracted from deprived or well-fed offspring, mothers respond more strongly to the chemical stimuli from the well-fed offspring and allocate more food towards them (Mas et al. 2009). More recent studies in wrens have shown that experimentally food-supplemented nestlings (nestlings in better condition) begged more intensely for food than nestlings that were not supplemented. Parents responded to the more intense begging signals of the nestlings in better condition, increasing their provisioning rate to them, but not to the offspring in poorer condition (Bowers et al. 2019). And in tadpoles, begging effort and performance were higher in more developed and higher condition tadpoles and actually declined with food deprivation (Dugas et al. 2017). Mothers allocated more food to more developed tadpoles as well as those who vibrated (a component of their begging behavior) at a higher speed.

Despite the encouraging results (so far) in support of the SoQ hypothesis over the SoN hypothesis, it is unlikely that there is a single explanation for the varied forms of begging behavior that have evolved across taxa. For example, some recent work in poison frog mimics that *does* account for the distinction between proximate-level wants and ultimate-level needs has found that begging is an honest signal of need (Yoshioka et al. 2016; Kilner and Johnstone 1997). Contrary to the predictions of the SoQ hypothesis, offspring not fed a supplemental diet over a certain period of time begged more intensely than offspring fed a supplemental diet during the same time period. Clearly, the literature on the evolution of begging is not settled and is in need of more empirical tests that consider more explanations and remain

unbiased about which one is correct. But the overwhelming theoretical and empirical consensus on the honesty of begging seems like it will stand uncontested, even if parent and offspring's genetic interests do have a nonoverlapping zone.

## Conclusion

While the bulk of begging research has focused on answering ultimate-level evolutionary questions, developmental perspectives on begging and quantitative genetic perspectives of parent-offspring interactions continue to enhance our understanding of the proximate mechanisms behind begging signals (Leonard and Horn 2005, Kölliker and Richner 2001). More recently, researchers have become interested in the endocrinology of begging, finding that hormones play a large role in regulating begging behavior in birds and inspiring research in other taxa (Smiseth et al. 2011). Innovations in genetic sampling and analysis will further our understanding of how this key parent-offspring interaction functions across taxa and bolster evolutionary claims. In addition, developmental and genetic perspectives can help to expand our understanding of begging evolution by inspiring questions about selection pressures at different life stages and how genetic variation in offspring begging is maintained despite selection. Additionally, research on begging has recently been expanding in scope to include taxa other than birds, and this is increasingly providing fertile ground for empirical tests of the extensive begging models that theoreticians have already developed.

## Behavior Modification

Kathleen N. Morgan  
Wheaton College, Norton, MA, USA

## Synonyms

Applied behavior analysis; Behavior therapy;  
Conditioning

## Definition

A set of procedures for changing behavior (through reinforcing it or subjecting it to extinction) that are largely based in the principles of operant conditioning.

## Introduction

Behavior modification refers to the application of a set of procedures (largely based in the principles of operant conditioning and rooted in classical

conditioning) in order to bring about changes in behavior. It is more frequently referred to in contemporary parlance as *applied behavior analysis*. Typically, the goal of behavior modification is to change behavior through an initial assessment of its functional relationship with the individual's environment. An understanding of the function of the behavior is then utilized to develop and deploy a set of controlled experiences (see below) that are aimed at meeting that function by means of a more desirable behavior. Behavior modification aims to reduce the frequency of an undesirable behavior and increase the frequency of desirable behavior and to bring about such changes with a minimum of aversive experiences for the individual whose behavior is being modified. Thus, behavior modification generally involves increasing the frequency of a desired behavior through the use of reinforcement and/or decreasing the frequency of an undesired behavior (or extinguishing it) through subjecting that behavior to extinction.

The phrase “behavior modification” was perhaps first suggested by the American psychologist Edward Thorndike in his text *Animal Intelligence* (1911), in which he makes frequent reference to the concept of “modifying behavior” through manipulation of the consequences to that behavior that an organism experiences. Through his work in observing how animals changed their behavior in response to their experiences, Thorndike derived what he called the “Law of Effect”: the tendency of a behavior with “desirable” effects – that is, one that is followed by a desirable consequence – to be repeated in the future, while behaviors that were followed by undesirable consequences tended to fall out of the individual's repertoire. The principles employed in behavior modification to bring about behavioral change are seated in the work of early “behaviorists” like Thorndike, as well as in the work of the Russian physiologist Ivan Pavlov.

## Principles of Behavior Modification Derived from Pavlov's Work

Pavlov had begun his scientific career investigating the contributions of the salivary system to digestion – work for which he was later awarded

the Nobel Prize in Medicine. As part of his procedures for that work, Pavlov had made visible the salivary output of dogs, through cannulization of their salivary ducts, which allowed for all saliva produced to be output directly into a collecting tube. Through this means, Pavlov was able to measure the amount and rate of output of saliva in response to different triggers (foods varying in texture and palatability) placed in the mouth of the dogs by his research assistants. What came to fascinate Pavlov over time is the observation that, with repeated experience, his dog participants began to salivate in response to the sight of the research assistants or of being placed into his research apparatus. He hypothesized that this change in salivation behavior in response to a previously neutral stimulus (such as the sight of his research assistants) was a consequence of the experience of that key stimulus reliably preceding the placement of food in the mouth. In his subsequent work on what he called “psychogenic” salivation, Pavlov documented more formally the experiences required to bring about a change in behavior in response to a given stimulus (the sight of the research assistants, in the original instance). A collection of his lectures published in 1928 details his work on this topic. With respect to behavior modification, Pavlov’s work on what has come to be known as classical conditioning is among the early demonstrations that intentional manipulation of experience could bring about long-lasting and predictable changes in an organism’s behavior – a point of view that is the essential base in the field of behavior modification.

Classical conditioning as a model for how some behavior changes with experience has been used to explain a variety of normal and abnormal behaviors in organisms. For instance, it has been used to explain how something like the sound of a box clicker or a whistle (what animal trainers typically refer to as a “secondary reinforcer”) can come to have a value to the animal hearing that sound. If the sound reliably precedes the presentation of a desired item or event (such as food or the opportunity to play with a favorite toy), the sound itself begins to be capable of sustaining the repetition of whatever behavior caused it to be presented.

Similarly, phobias and other fears have been theorized to develop through inadvertent classical conditioning. A sudden loud sound resulting from the banging of a loose door may cause a horse that had previously had no fear of that doorway to be no longer willing to pass through it. The sight of the doorway now predicts a possible frightening event (the loud and startling sound), and thus the doorway itself is now an object that elicits fear. The text below will shortly review some applications of classical conditioning as they are routinely employed in behavior modification. The practice of systematic desensitization – the gradual reduction of a conditioned fear response through slow, systematic pairing of the feared stimulus with responses incompatible with fear (such as relaxation) – is one way in which classical conditioning principles have been used to improve the lives of both human and nonhuman animals.

### **Operant Conditioning Techniques and Behavior Modification**

Additional evidence in support of the idea that behavior could be intentionally modified through control of experience came from the work of behaviorists such as John Watson (1930) and B.F. Skinner (1953). Watson and his research assistant Rosalie Rayner, for instance, applied the techniques described by Pavlov to induce fear of a rabbit in a human child (Watson and Rayner 1920), thus documenting that the phenomena described by Pavlov were applicable to humans as well as to nonhuman animals. Skinner in his work elaborated upon Thorndike’s “Law of Effect.” Specifically, behaviors that were followed by desirable consequences were “reinforced” – more likely to be repeated in the future; while those followed by undesirable consequences were “punished,” or less likely to occur in the future. Any consequence to a behavior that increased that behavior’s likelihood of being repeated in the future was a reinforcement, while any consequence to a behavior that decreased the behavior’s likely display in the future was a punishment. These constructs are further discussed elsewhere in this encyclopedia, but a brief review of them is presented here, to

facilitate the discussion of their explicit use in behavior modification that is to come in this particular encyclopedia entry.

How behaviorists have come to describe the consequences of reinforcement and punishment and their variants has led to no end of confusion, because of the common connotation of “bad” or “wrong” associated with the English word “negative” and the common connotation of “good” associated with the word “positive.” What the behaviorists mean by “positive,” however, is the *addition* of a stimulus, and what is meant by “negative” is the *subtraction* of a stimulus.

Behavior can be reinforced by *adding* an appetitive stimulus (positive reinforcement). For example, if a dog’s placing its hindquarters on the ground in response to the spoken word “sit” is followed reliably by a food treat or play with a favorite toy, the likelihood of that behavior occurring again in response to the word “sit” increases. *Subtracting* an undesirable stimulus such as social or physical pressure (an example of negative reinforcement) can *also* increase the likelihood of a behavior occurring again. Applying physical pressure with a heel or spur to the right flank of a horse when mounted will cause the horse to move its hindquarters to the left. The rider “reinforces” that step to the left by immediately removing the pressure of his/her heel. Over time, the horse will begin to move its hindquarters to the left in response to little more than detection of a contraction of the rider’s right calf; by doing so, the horse avoids the addition of unwanted additional pressure to the right side of its body. Thus, a behavior that the rider wishes to *increase in frequency* (moving the hindquarters to the left) has increased through the *subtraction* or removal of an aversive stimulus (the physical pressure of the rider’s heel against the horse’s side).

Behavior can be decreased in frequency (or punished) by *adding* an aversive stimulus (positive punishment). Applying a verbal reprimand (“No!”) or a slap with the hand in response to a behavior that one wishes to see decrease in frequency is an example of *positive* (as in something being *added* in order to change behavior) punishment. But *subtracting* an appetitive stimulus (typically one’s attention, or the liberty of the

trainee) can also be used to decrease the likelihood of a behavior occurring again. If the undesirable behavior is a dog’s jumping up on a human, one can decrease the frequency of this behavior by simply subtracting one’s attention – ignoring the dog until all four of its feet are back on the ground. Behaviorists refer to this consequence to a behavior as *negative* (as in something being *subtracted* in order to decrease behavior) punishment. In terms of their perceived rank order of aversiveness, positive reinforcement is considered to be the least ethically controversial consequence to behavior and negative punishment to be the least aversive form of punishment. The other two consequences (negative reinforcement and positive punishment) have been associated in the literature with fear, stress, and aggression in a number of species (see, e.g., Fernandes et al. 2017; Freymond et al. 2014; Hendriksen et al. 2011; McGreevy and McLean 2009; Innes and McBride 2008; Emurian et al. 1985) and are therefore not typically considered of value as modifiers of behavior in the practice of behavior modification.

Skinner (1953) recognized the application value of the possible consequences to behavior described above, inasmuch as such application could bring about desired changes in behavior in human clients presenting with behavioral problems. The primary practice for the treatment of such individuals at the time was psychotherapy in the form of talk therapy, still largely seated then in the psychoanalytic approaches of Freud and his followers. Skinner rejected Freud’s emphasis on constructs such as unconscious motivation which could not be empirically observed and verified, preferring instead to focus on the functional value of a given problem behavior to the individual engaging in that behavior and manipulating that value to bring about changes in behavior. Indeed, the Functionalism practiced by psychologists in America in the early 1900s still permeates behavior modification in practice today, as will be shown shortly.

### Functional Behavior Analysis as a Hallmark of Behavior Modification

Contemporary behavior modification still reflects Skinner’s valuing of the individual case and the

functional value of behavior as its sustaining impetus. The hallmark of behavior modification (applied behavior analysis) in practice is the use of an initial procedure for the evaluation of behavior referred to as *functional behavior analysis* (FBA). The protocols for such an analysis may vary, but generally FBA will include the following elements:

- An initial observation of the problem behavior, with no effort to intervene (unless the behavior is life-threatening). In this observation, the focus on the part of the observer is to try to identify possible triggers for, consequences of, and/or functions of the behavior. Specifically, an effort is made to clarify the *antecedent* to the behavior, the nature of the *behavior* itself, and the *consequences* of the behavior (these elements are sometimes referred to as the “ABCs” of functional analysis).
- Systematic manipulation of suspected antecedents, followed by observations of the results of those manipulations. Does the behavior occur at all following the suspected antecedent? Does it occur at a different rate or intensity? What do the consequences appear to be, if they are different from the original situation?

The FBA procedure is employed in such a way as to vary the order of testing of different suspect antecedents and functional consequences, in order to produce quantitative and qualitative data that can be used to come to a conclusion regarding the most likely triggers for and functional values of the problem behavior. This information is then used to design a training plan that is aimed at replacing or reducing the frequency of the problem behavior through control of its antecedents and/or changing of its functional consequences. Finally, such training plans generally involve the application of different positive reinforcement opportunities (as opposed to punishments); if punishment of any kind is employed, it is generally in the form of negative punishment.

As positive punishment is a consequence that by definition reduces the likelihood of a behavior's occurring again, the reticence to use punishment on the part of behavior analysts may

seem surprising. However, a behavior may also be eliminated from an individual's repertoire if it no longer results in the consequence that had served to sustain it. In the parlance of behavior modification, removing the functional consequence of a behavior effectively extinguishes the behavior; once the consequence is no longer forthcoming, the behavior undergoes extinction and eventually ceases to be performed. It is primarily through modification of what behaviors or aspects of a behavior are reinforced by the behavior modification practitioner and what behaviors are ignored that behavior change is brought about with a minimum of aversiveness.

A common means by which a change in behavior is brought about via changes in what is reinforced involves what is referred to in the behavior modification literature as *differential reinforcement*. As the term implies, the practitioner determines what behaviors he or she will reinforce going forward, as opposed to the problem behavior that had been perhaps inadvertently reinforced in the past. In some cases, the new behavior selected to be reinforced is intentionally one that cannot be engaged in at the same time as the original problem behavior is being performed. Such a strategy is called *differential reinforcement of an incompatible behavior (DRI)*. For instance, if the problem behavior in a dog is jumping up on a human, the human may choose only to reinforce (in the form of his/her attention, a treat, play, or a combination of these) behavior that results in all four of the dog's feet being on the ground. This latter behavior is incompatible with jumping up – the dog cannot be simultaneously jumping up and have all four feet on the ground. *Differential reinforcement of an alternative behavior (DRA)* is also as it sounds. In this practice, a behavioral alternative to the problem behavior is selected, and then that alternative is what is reinforced, while the problem behavior (or any other behavior) is ignored. As an example, consider a dog that indicates its wish to go outside by scratching violently at the door. An alternative to this behavior might be to nudge a bell with its nose to tell its owner that it wishes to go out. In DRA, the behavior of nudging the bell would be shaped and reinforced to the exclusion of any other means

that the dog may endeavor to employ in order to be let out. Other strategies for differential reinforcement include *differential reinforcement of other behavior (DRO*; reinforcement of any behavior other than the problem behavior) and *differential reinforcement of lower rates of behavior (DRL*; reinforcement of lower rates of a given behavior, with a goal of reducing but not eliminating the frequency of that behavior).

#### The Application of Behavior Modification to Nonhuman Animal Behavior

For most of its history, behavior modification as it has been described here has been used to reduce problem behavior and/or to increase the frequency of desirable behavior in humans. For example, the techniques of FBA have been used with great success to reduce rates of self-injurious behavior and increase rates of pro-social behavior in children on the autism spectrum (for a recent review, see Newcomb and Hagopian 2018).

However, others have seen the utility of such systematic assessments and training protocols designed specifically to respond to these assessments as having equal value when applied to non-human animals. For instance, in the late 1970's, Hal Markowitz (then Director of Zoological Research at the Portland Zoo in Oregon) observed what he considered to be an undesirable rate of abnormal stereotypic behavior and overall lethargy in zoo animals. Much as would a behavior modification practitioner, Markowitz made careful observations of the apparent functions served by the stereotypic behaviors he saw (such as pacing or rocking) and then endeavored to put into place modifications to the animal's environments that provided more valuable reinforcement for alternative behaviors. For instance, he trained animals to use puzzles to gain access to food or to receive an opportunity to chase an automated "prey" item (see Markowitz 1982, 2011 for a review of some of this work). Markowitz's work was foundational in the field of environmental enrichment, and it was also an early demonstration of the applied value of systematic behavior analysis and modification for improving the lives of nonhuman animals.

Zoos continue to be one of the common environments in which the practice and principles of

behavior modification are applied to nonhuman animals (Forthman and Ogden 1992; Bloomsmith et al. 2007; Maple and Segura 2015). In one such example, a chimpanzee who was being housed in isolation for a variety of health reasons had taken up spitting and throwing feces at human passersby. Potential contingencies supporting these undesirable behaviors were tested, and a program of DRA was employed in conjunction with extinction that ultimately reduced the frequency of these problem behaviors by 83% (Martin et al. 2011). Similarly, functional analysis of aggressive behavior in a captive lemur revealed that human attention was the primary reinforcing contingency. Removing this contingency and reinforcing alternative behavior successfully reduced rates of aggression in this individual (Farmer-Dougan 2014).

Self-injurious behavior (SIB) – such as hair pulling, self-biting, or feather plucking – is another behavior problem sometimes observed in captive animals. Often, such behavior is inadvertently reinforced by attention on the part of an animal's caregivers. Behavior modification techniques have been used to eliminate or reduce the frequency of SIB. In one example, self-biting and hair pulling were the problem behaviors observed in a female olive baboon. Systematic functional analysis suggested that inadvertent positive reinforcement in the form of attention from caregivers was supporting the problem behavior. It also revealed several low-frequency behaviors that were identified as preferred alternatives to the SIB. A training program was instituted that reinforced these alternative behaviors with the attention that had previously been given to the problem behavior. The results were an increase in the alternative behaviors and decrease in the SIB (Dorey et al. 2009).

Similarly, feather plucking in a zoo-housed black vulture, when subject to functional analysis, was found to be reinforced by contingent attention from caregivers. Eliminating this attention and implementing a DRO reinforcement strategy eliminated feather plucking in this animal (Morris and Slocum 2019).

Behavior modification techniques have also been used with success in domestic species.

In one novel approach to functional analysis, a survey of 128 dog owners was conducted to try to identify contingencies that might maintain stereotypic behaviors in pet dogs. Owners reported a wide variety of antecedents to the onset of stereotypic behaviors such as circling or light-chasing. Follow-up studies with several additional dogs revealed that owner attention was the functional reinforcer for stereotypies in two of the dogs, and sensory stimulation reinforced the problem behaviors in two others. DRO employed to reduce the problem behavior was successful but in some cases only if the owner was not the trainer. The authors conclude that a variety of functions might be served by stereotypic behavior in pet dogs and that a “one-size-fits-all” program treatment may not be appropriate (Hall et al. 2015).

In another study of four dogs presenting with the problem behavior of jumping up on people, functional analysis revealed several possible contingent reinforcers, such as attention from the human and access to a desired item that the human might be holding. Removal of these contingencies reduced the rate of jumping up behavior in all dogs (Dorey et al. 2012). Similarly, functional analysis was used to determine reinforcing contingencies in a study of three dogs living in an animal shelter and displaying problem behaviors such as leash pulling and aggression. Subsequent training to eliminate identified contingencies reduced the problem behaviors and increased the perceived adoptability of the dogs (Winslow et al. 2018).

Classical conditioning procedures have also been used to modify behavior in dogs, particularly to reduce fear and anxiety. The process of systematic desensitization has been successfully used, for example, to treat separation anxiety in dogs (Butler et al. 2011). The procedure entails exposing the animal to low levels of the anxiety-provoking stimulus (perhaps just the owner picking up his or her keys), and then rewarding non-anxious behavior with immediate praise and interaction with the owner. The process of separation from the owner is gradually expanded until the dog is able to tolerate that separation without a return of the anxious behavior.

Counter-conditioning has been used similarly to treat separation anxiety in dogs (Rogerson 1997). In this procedure, the anxiety-provoking separation from the owner is paired with conditions conducive to relaxation (such as the presentation of a desired food). The assumption here is that fearfulness and anxiety are incompatible with relaxed eating. Repeated exposure to the pairing of the previously anxiety-provoking situation of separation from the owner and the relaxed opportunity to eat a desired food item replaces that anxiety with a more desirable emotional state.

Horses have been another domestic species to benefit from the application of behavior modification techniques. In one study, DRO was used to successfully reduce pawing of the ground in three horses (Fox and Belding 2015). In another, biting and chewing in two horses were similarly reduced through the use of DRO (Fox et al. 2012). A third study showed that differential reinforcement was effective in improving trailer loading and reducing inappropriate behaviors in this context in four horses (Slater and Dymond 2011).

Behavior modification techniques differ from many other approaches to changing behavior in the willingness to focus on the individual case. Careful and systematic assessment of the antecedents of a problem behavior, the precise nature of that behavior, and the consequences that suggest its function are used to inform well-designed training protocols tailored to the individual case, with the overall goal of reducing problem behavior through the use of a minimum of aversive experiences and increasing desirable behavior through positive reinforcement. The literature suggests that these methods are effective in bringing about desirable changes in behavior with a minimum of adverse effects. Clearly, the field of behavior modification has much to contribute to the overall behavior and well-being of non-human animals (Overall 2012).

## Behavior Systems

Robert Ian Bowers  
School of Psychology, University of Minho,  
Braga, Portugal

## Beginnings in Ethology

Nikolaas Tinbergen (1942) began to speak in terms of systems of behavior in his first manifesto of ethology. As there are systems of respiration and systems of digestion, for instance, in which multiple chores are accomplished in coordination by different parts to perform a complex function, there can be said to be systems of behavior that collectively accomplish complex chores such as feeding, finding mates, avoiding pain, and perhaps less obvious functions as well, such as play, grooming, or sociality. Tinbergen (1942) stressed that behavior has an organization and that this organization is hierarchical (Fig. 1).

## Behavioral Context of Behavior

At the core of a behavior systems approach is concern for how the various behavioral propensities of an animal's repertoire interrelate. Feeding, for instance, requires the unfolding of a complex

sequence of behaviors. Focus on the interdependence of related behaviors sets behavior systems approaches apart from more analytical approaches in biology and psychology that treat behavioral variables as discrete and independent. What began as a hypothesis about behavior being hierarchically organized matured into a set of methods concerned specifically with the organization of an animal's behavioral repertoire.

While the rest of ethology grew progressively more analytical over the twentieth century, Gerard Baerends (1941, 1976) retained focus on sequential relations among behaviors, how different behaviors interrelate temporally, and which situations lead to which responses. In Baerends' approach, one monitors behavior of animals in the wild for extended periods. Monitoring can be continuous or by sampling at regular intervals. Focus on the interrelation of behavioral forms invites use of advanced statistical or modeling techniques to identify patterns of concurrence. To clarify causation, field experiments are conducted where possible and necessary.

Although behavior systems approaches that followed differed from Baerends' in many respects, a central concern with situating behavior in a behavioral or motivational context is held in common.

## Model of the Animal

Behavior systems approaches involve multiple kinds of theory. At its most general, a behavior systems approach comprises a set of assumptions and a way of talking about them. It is not a hypothesis to be tested, but a way of approaching behavior that embraces its complexity, focusing specifically on its organization. It is an interpretive and investigative strategy or framework.

One output of this strategy is a model of how the animal's behavior is organized. Figure 2 shows one such model. This model of the animal is also a kind of theory, but still not a theory in the familiar terms of species-general or system-general capacities or processes, like learning or reasoning, but of the species and system itself. This produces an apparent problem: such models are not in a form

**Behavior Systems, Fig. 1** Tinbergen's 1942 hierarchy of moods model of the reproductive drive in stickleback fish (From Tinbergen 1942)

that is readily interpretable in terms of more common theories or familiar interpretive frameworks. While pondering the detailed models of herring gull nesting (Fig. 2) or digger wasp provisioning (Baerends 1941), which sometimes look like wiring diagrams, one is surely impressed, and perhaps awed by the work involved, but may then wonder what is to be done with such specific models of relatively obscure animals and systems.

The detailed models produced by such analyses are more than mere curiosities of natural history. With a theory of the animal and system in hand, one then has a basis upon which to situate further analyses and test hypotheses in more familiar terms, such as a theory about some cognitive phenomenon. Analyses of abstractly phrased capacities or processes can be embedded within an independently developed model of the specific animal's behavioral organization. This way behavior systems solves a problem for psychology that arises in any preparadigmatic science:

some description should precede assessment of theories, but the terms of description (what is measured and what it means) are determined by the theory. Thus, without an independent foundation, abstractly phrased theories of capacities specify the terms of their own assessment. For instance, checking a food trough is often taken as an indicator of expectation of food, without concern for when that animal might otherwise perform the same behavior. A behavior systems perspective solves this dilemma by providing a theoretical basis for description in terms specific to the animal, system, and circumstance.

This model of the animal approach, by which one first describes the structure of the behavior in a given system and then uses this to situate analyses of phenomena of interest, is a thermomorphic approach (Timberlake 2007). It provides a manner of foundation, but unlike chemistry, for instance, which has just one periodic table, the kind of foundation provided by a behavior systems

**Behavior Systems, Fig. 2** Baerends' model of nesting behavior of herring gulls (From Baerends 1976)

framework is specific to the animal, system, and circumstance. This can be aptly contrasted with common alternative interpretive frameworks. One common way of interpreting behavior is by anthropomorphism, wherein one uses suppositions about human cognition or behavior as a model to provide a basis for describing or understanding the behavior of other animals. The dangers of anthropomorphism have been aptly

identified (as well as solutions to some of them), although explicit and implicit anthropomorphic approaches remain prevalent in animal cognition research. Another common approach bases analyses on normative theories. A fault with normative approaches is that they permit interpretation only of behaviors that are clearly and directly instrumental. The benefits of normative approaches can be recovered, however, by

embedding such analyses in a behavior systems framework. In general, abstractly phrased approaches concerned with capacities tend to permit interpretation of only a very limited range of behavioral variables. A primary gain of alignment with a behavior systems approach is an ability to interpret a broader array of behaviors.

Behavior systems may be said to involve yet another level of theory insofar as one views a motivational system as a model the animal holds about the world. This aligns behavior systems, at least superficially, with “theory theories,” views that attribute a naïve theory to the animal, such as a “theory of mind” or “naïve physics” or *Umwelt*. A similar point can be made regarding some graphical model-based views, including those that assume that the animal forms a representational model of relevance relations. Caution is warranted when drawing analogies between naïve theories or graphical models, and motivational systems, for the terms are typically different. Still, such analyses may often be complementary.

## Evolution

Behavior systems is an evolutionary approach. Evolution is used to permit a connection with ecological pressures, similar to other evolutionary approaches in psychology. However, focus on systems and behavioral interrelations, as opposed to discrete behavioral traits, sets it apart from typical evolutionary approaches. The benefit of restricting evolutionary hypothesizing to interrelated components of systems is that it narrows focus on local selection pressures. Modeling the structure of behavior systems relies heavily on evolutionary thinking, which it uses as a source of hypotheses, and to provisionally fill the many gaps in knowledge concerning perceptual, motor, and motivational factors. Admittedly, behavior systems are highly complex, with sensory, motor, and motivational components evolving in tandem, and this produces substantial uncertainty regarding the specific selection pressures and their impact on evolution. This problem, however, is not unique to behavior systems approaches.

## Behavior Systems/Neural Systems/Motivational Systems

Although behavior systems theory was developed within ethology as its leaders were working to establish ethology as a science of observable behavior, the earliest behavior systems models referred to drives or moods or nervous centers. In the context of sciences of behavior growing progressively uneasy about internal variables, this reference to unobservables drew fire. An early response to this was to talk literally about behavior, as contemporary ethology does. One sees this approach in Baerends’ work and thinking, and it is the more typical approach to take among ethologists.

Tinbergen’s (1951) own conception of behavior systems, in contrast, was primarily concerned with nervous structures. This view is echoed in the writing of later ethologists, as well as neuroscientists (e.g., Fanselow 1994). This conception of behavior systems has been criticized as physiologizing, but it has also produced some successes. Michael Fanselow (1994), for instance, applied such an approach to produce a model of defensive behavior in rats with reference to specific neural structures.

A third way of conceiving of behavior systems is closest to the initial formulations, in motivational terms. This is the more common approach among psychologists, notably William Timberlake (1983a, 1994, 2001) and Michael Domjan (1994), and the approach that has undergone the most development. This conception has provided the basis for a theory of learning (below) and opens behavior systems analyses to investigation of cognition more generally.

One difficulty faced by views of behavior systems phrased in strictly behavioral terms, as opposed to motivational, is that the specific patterns of behavior an animal exhibits appear to depend heavily on the response supporting characteristics of the apparatus and the details of the procedure. Different circumstances may afford different manifestations of a given motivational status, and this adaptability to changing environmental demands is an important part of Timberlake’s approach, which allows a behavior

systems model to remain relevant outside of an animal's specific niche. The niche itself might vary widely. A strict behavioral phrasing appears to imply that behavior will be brittle, not adaptable to changing circumstances, whether considering the variability encountered within the niche or between the niche and evolutionarily unforeseen environments like a Skinner Box.

Baerends generally adopted an ethologists' attitude and attempted to develop his thermomorphic models as situated within the species' niche and test them there. In such environments, the distinction between motivational and behavioral systems can be blurred. Timberlake, in contrast, primarily remained in the laboratory. He stressed that behavior exhibited in laboratory settings is no less natural or relevant to understanding the animal. Timberlake recognized the importance of the specifics of the apparatus and procedure for producing specific patterns of behavior, but there is no pretense, by this view, that a more naturalistic setting would necessarily be more appropriate. Where one is interested in helping to make sense of laboratory findings, a replication attempt may often be the place to start. Specific aspects of the apparatus may limit or otherwise constrain behavior in ways that produce patterns of behavior that appear to support some theory artificially (Timberlake 1983a). Identifying such cases has historically been among the clearest critical successes of behavior systems work.

Note that by Timberlake's usage, a behavior system refers not only to its motivational component but to perceptual and motor components as well. The motivational component receives focus by this approach, depending on the specific problems addressed, but it is remembered to be embedded within the motor and perceptual realities of the animal. Behavior will depend on all of these factors, as well as the current circumstance.

### Timberlake's Theory of Learning

William Timberlake (1983a) applied a behavior systems approach to learning, and the resultant theory (confusingly) took the name, behavior

systems theory. The primary innovation was a shift in the conception of the unconditional from discrete stimuli to systems. By behavior systems theory, learning is a means of finding a match between the structure of one's environment and the structure of internal motivational systems. Tinbergen and Lorenz had talked about learning in similar terms, but left these intuitions undeveloped.

By a range of views, terminal feeding behaviors are reinforced through association with acquisition of food. By a behavior systems perspective this is only a part of a more complex system of behavior, the rest of which may be unsupported or even prohibited by the apparatus, or just not measured, for the purpose of isolating specific, quantifiable responses. Rather, when animals learn about associations in their respective worlds, they are learning how stimuli fit into a behavior system. An unconditional stimulus engages not just a single unconditional response but a whole motivational complex. An associated cue is fit into this complex.

### Three-Mode Model

Timberlake (1990, 2001) presented the three-mode model which begins by dissociating three phases of system-specific behavior: consummatory, focal search, and general search. Earlier thinkers (Craig 1918; Konorski 1967; Bindra 1961) had dissociated consummatory (or terminal) from appetitive (or preparatory) behaviors. Consummatory (derived from the Latin, *cōsummare*: to complete, accomplish) responses are behavioral end points, what happens when the goal is in hand, for example, killing the prey or copulating. These are the responses most typically in focus in conditioning studies, such as a pigeon's pecking a light that signals food. Appetitive behavior consists of the set of behaviors that lead the animal to such an end, such as hunting or courting. The three-mode model divides appetitive behavior further into focal search and general search. A predator's behavior changes strikingly when it spots prey. At that moment, the predator enters focal search mode, and they move in to kill, now focused on a particular target. However, the hunt had started long

before this moment, as the animal exhibited a very different set of behaviors: general search. For some predators, general search manifests as roaming, some lie in wait. Each step in this sequence biases the animal differently in order to produce the conditions for the next phase, bringing the hunter progressively to a specific end. The animal solves a complex problem by dealing in sequence with just one segment of the problem at a time. Similarly, feeding on berries, one shifts between exploiting the current patch, searching locally for the next berry on a bough (focal search), and exploring, leaving the current patch to find the next (general search). This example accentuates the counter-intuitive point that feeding-related general search behavior often moves the animal away from food.

In addition to the response producing characteristics of motivational systems, Timberlake's approach stresses the response supporting characteristics of apparatus and procedure. Conditional responding can manifest in very different ways that depend not only on the significance the cue acquires to a system of behavior or motivation, which is related to the motivational significance of the US, the system evoked, involving such factors as temporal or spatial distance from the US, and reliability of the CS-US relation, but also on the manner of response the environment affords. A consummatory conditional response is most likely when the CS is close, recent, and reliable in relation to the US. A general search CR is expected with long CS-US delays (e.g., Akins et al. 1994). If the CS is another rat, the behavior elicited is the social response connected with feeding; if the CS is a protrusion from the wall, manipulation and biting; if a moving sphere, chasing and grabbing and carrying (Timberlake and Grant 1975; Timberlake et al. 1982; Timberlake 1983b). Embedded in this analysis is a critique of general-process approaches insofar as they lose sight of how their procedures

and apparatus produce patterns of behavior (Timberlake 1983a). More positively, behavior systems theory permits interpretation of a broader range of response forms that occur in conditioning studies and bringing these behaviors into an analysis gives it depth.

Although the three-mode model was developed in the context of feeding in rats, models with the same essential basis have been applied with success to sexual behavior in Coturnix quail (Domjan 1994) and fear behavior in rats (Fanselow 1994).

Francisco Silva and Timberlake extended the three-mode model in an important way that places focus on the specific effects of temporal and spatial factors on motivational interactions. Figure 3 illustrates change in strength (vertical axis) of the three modes in relation to each other over a dimension of CS-US proximity (horizontal axis). This proximity dimension brings conceptual unity of various factors in conditioning studies, including temporal, spatial, correlational, and evolutionary relatedness. This basic model and its predictions have proven surprisingly robust in application to conditioning phenomena (Silva et al. 1998a, b; Timberlake 2001).

## Connections with Other Sciences

Behavior systems theorists have long stressed integration of sciences and viewed behavior systems as means of accomplishing this. For Tinbergen (1951), it served as a theoretical link between ecological and physiological analyses and the basis for his first attempt to bring physiology into ethology. Timberlake's extensions of behavior systems (Timberlake 1983a; Timberlake 2001) provided a theoretical basis for principled integration of ethology with psychology. Both thinkers were also dedicated discipline bridge builders,

### Behavior Systems,

**Fig. 3** A depiction of the Three-mode model (From Silva et al. 1998a; Timberlake 2001)

investing heavily throughout their careers in providing institutional infrastructure to enable integration of sciences.

Throughout its history, depictions of behavior systems took the form of networks of interrelated drives or behaviors. These networks represented hierarchical organization, which was stressed in the initial presentations (e.g., Fig. 1), but behavior systems theorists otherwise took little inspiration from network theory. Similarly, the reference to systems was not principled application of systems theory. These potential connections remain unplumbed.

Gordon Burghardt has suggested that a behavior systems approach might be applied to emotions (Burghardt and Bowers 2017). The suggestion appears promising, but it awaits empirical support.

Robotics has contributed to the study of animal behavior methodologically by providing an independent means of testing hypotheses, and the two fields connect in the areas of synthetic biology and artificial life. Inspiration specifically from behavior systems thinking, particularly hierarchical organization and task decomposition, is apparent in the layered architectures used in some robotics communities, notably subsumption architecture (Brooks 1986). Layered architectures produced an initial boom in robotics research, permitting behavior-based robots to succeed at tasks that had stumped earlier generations of robots. However, the initial success was followed by a bust, which may have been helped by better communication between these fields.

In general, a behavior systems approach can be viewed as a strategy for addressing questions throughout psychology, a portable foundation to carry around that is based on a model of the animal and system, rather than of a general capacity (e.g. memory, causal reasoning), one that gives some guidance on how to apply abstract theories to real animals.

## Synonyms

[Behavioral plasticity](#)

## Definition

Behavioral adjustments in response to external or internal stimuli.

## Introduction

The ability to respond to changing conditions in innovative ways is a key evolutionary adaptation of humans and other animals (Lefebvre 2013). This behavioral flexibility, which describes the changes in an individual's behavior in response to environmental stimuli, is often used synonymously with behavioral plasticity (e.g., Brown and Tait 2010; Holekamp et al. 2013; Wong and Candolin 2015). Behavioral flexibility is sometimes erroneously confused with behavioral

variation when comparisons of behavioral differences among individuals of the same species across space are conflated with those of the same individuals over time (Strier 2017). However, while behavioral flexibility necessarily produces behavioral variation, the converse is not always true because behavioral variation can also arise as a result of other mechanisms, including local directional selection pressures or drift. In theory, the strongest evidence for behavioral flexibility comes from behavioral changes that track environmental or social stimuli and that can reverse in the absence of the stimuli that elicited the responses initially. Comparisons across individuals, groups, or populations of conspecifics can yield evidence of intraspecific behavioral variation, but temporal comparisons are required to identify the existence of behavioral flexibility.

Behavioral flexibility can be described as an individual or a species-specific trait. Differences among individuals in their levels of behavioral flexibility are often attributed to personality, coping styles, or behavioral syndromes, which are correlated behavioral responses (Coppens et al. 2010). Intraspecific behavioral differences across groups or populations may reflect responses to local environmental conditions with either or both learned and genetic components, whereas interspecific behavioral differences have an additional effect of phylogeny, which can either facilitate or constrain plasticity (Kappeler and Kraus 2010; Kappeler et al. 2013). There is also increasing evidence that individual differences in behavioral flexibility may reflect experiential differences at earlier stages of life, which can either increase or decrease plasticity (Stamps 2016; Stamps and Biro 2016).

The ability to adjust one's behavior in response to local social and environmental conditions is generally considered to have direct fitness consequences (Coppens et al. 2010). Behavioral responses to changing conditions would be particularly advantageous when the changes occur faster than the rate at which behavioral evolution could occur. Presumably, natural selection would favor the capacity for behavioral flexibility whenever local conditions are subject to frequent but unpredictable change or fluctuations. Variation in the conditions that both elicit specific behavioral

responses and select for behavioral flexibility could account for behavioral variation across groups and populations of the same species, as well as for differences in the degree of behavioral flexibility across species. Genetics, developmental constraints, and life history characteristics also affect both individual and species-specific differences in behavioral flexibility. Correlated behavioral responses can limit the flexibility of responses to particular stimuli, even to the point of being or appearing to be nonadaptive (Sih et al. 2004).

Distinguishing between conservative, species-specific patterns of behavioral flexibility and intraspecific, population or individual variation in behavioral flexibility remains a challenging area of investigation (Coppens et al. 2010; Strier et al. 2014). Not surprisingly, high levels of behavioral flexibility have been associated with long-lived, large-brained, highly social animals, such as primates, whose slow developmental rates and overlapping generations provide extended opportunities for social learning. These life history traits also increase the likelihood that individuals will experience fluctuations in social, demographic, and ecological conditions over the course of their long life spans, making the ability to respond to new or changing stimuli highly adaptive. However, the same slow life history traits that make behavioral flexibility so adaptive for primates may also contribute to their greater extinction risks compared to other mammals with relatively faster reproductive rates and shorter generations (Lindshield 2017).

## Ecological Flexibility

Seasonal changes in ambient conditions, such as temperature, rainfall, or day length, can alter the availability and distribution of critical resources such as food, water, or mates and result in predictable behavioral changes. These include shifts in the allocation of time and energy devoted to different activities, as well as in changes in diets, patterns of ranging and habitat use, and the types and rates of social, reproductive, and thermoregulatory behaviors. Among primates, seasonality in food availability typically results in different

combinations of adjustments in diet, ranging, and grouping patterns that are at least to some extent predictable based on the degree of dietary specializations (Strier 2016). For example, species with highly specialized diets are more likely to adjust their ranging and grouping patterns than species whose more generalized diets permit them to maintain stable social groups despite scarcities in their preferred food sources. Sympatric species that occupy different feeding niches may respond differently to identical stimuli, whereas different populations of the same or closely related species typically differ more in the degree of their responses relative to local conditions than in the kind of their responses.

The repertory of flexible behavioral responses elicited under normative, seasonal fluctuations may be inadequate to meet the challenges posed by extreme or unpredictable climatic events such as prolonged droughts and major hurricanes. These kinds of extreme events are known to be responsible for high levels of mortality in wild primate populations, and they are predicted to become increasingly common as a consequence of global climate change (Meyer 2017). Although some animals are capable of shifting their geographic ranges as climate and vegetation change, habitat loss in general and fragmentation in particular represent major barriers for others, such as the majority of primates, which are largely dependent on forests. Exceptions to this, such as macaques (*Macaca* spp.) that have adapted to urban settings, have been distinguished as “weed” species specifically because of their exceptional ecological flexibility (Richard et al. 1989).

## Social and Demographic Flexibility

Many animals adjust their grouping patterns in response to ecological stimuli. These adjustments can be distinguished into aggregations, such as the antipredator tactics that result in the formation of schools of fish or flocks of birds, versus social groups, which are comprised of two or more individuals that differentially associate and interact with one another.

Nonetheless, aggregations provide opportunities for social interactions, and conversely, members of social groups may fission into different combinations for varying periods of time, thereby disrupting their associations and opportunities to interact. Such “fission-fusion” societies are observed in primates such as chimpanzees, bonobos, and spider monkeys, as well as in dolphins, elephants, and spotted hyenas, and are generally predicted by ecological variables (Aureli et al. 2008).

Some of these species (e.g., chimpanzees, dolphins, and elephants) with fission-fusion societies also possess large brains relative to their body sizes and sophisticated cognitive abilities, but there is currently no clear evidence of a generalized link between social flexibility and cognition (Aureli et al. 2008). Indeed, although fission-fusion societies may require particular skills, such as memory to keep track of the status of social relationships without continuous access to one another, there may also be equally complex but different cognitive skills required for negotiating and repairing the strains on social relationships that are more likely to arise as a result of the higher frequency of interactions in cohesive groups.

The occurrence of cohesive groups versus fluid, fission-fusion societies, along with many other features of animal social and mating systems, has been explained by ecological variables including the availability and distribution of food and other resources (e.g., Jarman 1974; Emlen and Oring 1977; Wrangham 1980). The size and composition of groups simultaneously affect individual social options and are affected by demographic variables such as population-wide sex ratios and population densities, which can change rapidly over the duration of individual lifetimes, and by life history variables such as reproductive rates and dispersal regimes, which tend to be phylogenetically conservative (Strier 2008, 2011). Demographic changes have been implicated in switches between predominantly single-male and predominantly multi-male groups and in deviations from both male-biased and female-biased dispersal regimes. In addition, among primates, the flexibility to switch between

cohesive and fission-fusion groups is also associated with both high demographic variance and female or bisexual dispersal (Strier et al. 2014). For example, a sixfold increase (from 50 to more than 300 individuals) in the size of an isolated population of northern muriqui monkeys (*Brachyteles hypoxanthus*) inhabiting a protected forest fragment in southeastern Brazil has been implicated in two successive behavioral changes (Strier and Mendes 2012). First, the doubling of one study group (from 23 to 57 individuals) over a 15-year period was accompanied by a shift from cohesive to fluid, fission-fusion associations, presumably to minimize per capita travel costs in the quest for food and direct feeding competition. Continued population growth over the next 15 years was subsequently associated with an expansion of the muriqui's vertical niche to include increasingly frequent use of the ground and terrestrial resources. Although the initial shift was probably stimulated by ecological necessity, terrestrial behaviors spread along social networks, and the diversity of terrestrial activities expanded to include resting and socializing, reflecting a further extension of their behavioral flexibility (Tabacow et al. 2009).

Another example of pronounced behavioral flexibility comes from the social transition documented in a troop of wild olive baboons (*Papio anubis*) after its most aggressive males succumbed to a respiratory disease (Sapolsky and Share 2004). The remaining troop members adopted more relaxed, peaceful relationships, with higher rates of grooming and other affiliative behaviors that persisted despite the immigrations of males from other troops with less pacific traditions.

Both the adoption and persistence of the baboon's relaxed sociality and the spread of the muriqui's terrestrial tradition bear similarities with processes commonly associated with cultural innovation and transmission (Laland and Hoppitt 2003). Other forms of behavioral flexibility, initially stimulated by ecological or demographic stimuli and enhanced through learning and sociality, are also considered to have been fundamental steps in early hominin behavioral evolution (Meindl et al. 2018).

## Flexibility to Anthropogenic Changes

Behavioral flexibility is a critical component of the adaptive capacity of animals to respond to rapid and unpredictable change. However, our understanding of these capacities is limited by an absence of detailed comparative data on the behavioral repertoires of most animal species. Even when comparative data exist, our ability to distinguish behavioral flexibility from other sources of behavioral variation is often limited by the short temporal scales over which the comparisons can be made (Strier 2017).

Tragically, contemporary field studies of the behavior of wild animals are now faced with the challenge of distinguishing behavioral adaptations that have been selected over evolutionary time, from behavioral responses to rapidly changing conditions as pressures from human activities encroach on animal habitats and populations (Hockings et al. 2015; McLennan et al. 2017). The alarming rapidity of these anthropogenic changes often precludes evolutionary adaptations. While some species may be able to adjust their behavior and even keep pace with rapid climate changes (Beever et al. 2017), the prospects for many others remain grim. The selection of sub-optimal habitats following rapid environmental change can lead to ecological traps (Hale and Swearer 2016), a subset of the broader phenomenon of evolutionary traps in which past adaptive behavioral responses to environmental stimuli are detrimental, or maladaptive under current conditions, and can lead a population or a species to extinction (Schlaepfer et al. 2002; Robertson and Chalfoun 2016). Thus, understanding both the potential for behavioral flexibility and its fitness consequences has important implications for the conservation of biodiversity.

## Conclusion

According to the IUCN's best estimates ([http://cmsdocs.s3.amazonaws.com/summarystats/2018-1\\_Summary\\_Stats\\_Page\\_Documents/2018-1\\_RL\\_Stats\\_Table\\_1.pdf](http://cmsdocs.s3.amazonaws.com/summarystats/2018-1_Summary_Stats_Page_Documents/2018-1_RL_Stats_Table_1.pdf) 30 January 2018), 41% of all amphibians, 13% of birds, and 25% of mammals

were threatened with extinction as of 2017. For major groups, such as primates, these percentages may already be as high as 60% (Estrada et al. 2017). High levels of behavioral flexibility may buffer some animals from extinction, but ultimately it will require greater behavioral flexibility by humans than we have so far expressed to reduce these impending threats.

## Behavioral Genetics

Juliane Friedrich

The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Midlothian, UK

## Introduction

Genes are the basis of all life, and variations in the genetic code significantly affect a variety of physiological traits in animals, e.g., body confirmation traits, production and fertility, or the susceptibility to diseases. Behavior, in contrast, resembles rather an action or reaction than a physiological trait, so does the concept of a genetic contribution to trait variation between individuals also apply for behavior?

Probably one of the first evidence for a genetic background of animal behavior can be found in the evolution and breed history of the domestic dog (*Canis familiaris*). In the course of the domestication of dogs, the traits under selection, be it natural or artificial, were also of behavioral nature, e.g., tameness and attachment to humans and later

hunting and herding behavior. Subsequently, in the formation of the different dog breeds, the modern dog as we know it today, was shaped among others by selecting dogs with favorable personalities.

Dmitry Belyaev demonstrated this process of behavioral selection in canid domestication in a similar species, the silver fox (*Vulpes vulpes*). In his selection experiment beginning in 1959, farm foxes were selected for tameness only in a standardized environmental setting: after birth and weaning, pups were caged with litter mates and kept under minimal contact with humans. In the first months of their lives, a pups' tameness was evaluated in a series of behavior tests and only the ones with the highest scores for tameness were selected for breeding. The selection over multiple generations resulted in a shift towards tame behavior, with a growing percentage of animals within every generation that expressed docile behaviors. Based on these observations Belyaev concluded that behavior has a genetic background to some extent. After multiple decades of selection, experimenters refer to these animals as domesticated foxes, as they were eager to establish human contact, they whimper to attract attention and sniffing and licking experimenters like dogs (Trut 1999).

Now, the idea that genetic variations besides environmental factors and individual experiences contribute to the way an animal behaves in response to external stimuli and in certain situations is widely accepted. However, to which extend behavior variations are influenced by either genetic or non-genetic (environmental) factors is excessively discussed in the nature vs. nurture debate. More likely than exclusive influences of nature (genes) or nurture (environment) is an interaction between both factors: genetic variants can determine how environmental stimuli that trigger behaviors are received and processed (e.g., by modifying the sensory system) and the environment can alter the inner state of an animal (e.g., a lack of food leads to hunger) which in turn can regulate gene expression (Bendesky and Bargmann 2011).

In the era of molecular genetics, research on behavior genetics in animals can evolve from descriptive observations from selection

experiments to the detection of causal variants and molecular mechanisms involved in the genetic architecture of behavior. Comprehensive data from various molecular levels, e.g., genome, transcriptome, and metabolome information, can now be used to meet the still growing interest in the genetic contribution to behavior variation in animals: dissecting the genetic background of animal behavior has its relevance in animal welfare in domesticated species (e.g., breeding for stress-resistance in livestock), can give insights into the evolutionary importance of behavior in wild populations, and finally, can provide general information which might be related to behavioral conditions or psychological disorders in humans.

In the following, the basis of the genetic architecture of animal behavior is described and relevant candidate mechanisms with known influence on behavior variation in animals are introduced. Then, methods for behavior phenotyping and the subsequent genetic analysis are presented and examples for the genetic contribution to specific behavior traits or patterns are given. Additionally, the interactions between non-genetic (environmental) and genetic factors in relation to behavior variation are presented. In the conclusion, the challenges and perspectives of animal behavior genetics are briefly discussed.

## The Genetic Architecture of Behavior

Behavior itself is a complex trait and so is its genetic architecture. A Mendelian inheritance pattern for behavior traits, meaning that a trait variation is controlled by one locus only, is rare. Instead, the inheritance of most behavior traits is of polygenic nature, i.e., there are multiple genetic loci contributing to the observed behavioral differences of which many have a small affect and just a few have a moderate or even a large effect (York 2018).

To which proportion behavior has a genetic component is highly variable for specific behavior traits: genetic loci associated with courtship or feeding behaviors explained significantly more phenotypic variance in different species than genetic loci associated with other behaviors

(York 2018). It is assumed that behavior traits like courtship, which are positively correlated with the reproductive success and thus the genetic fitness of an individual, might be involved in evolutionary processes and subsequently are more likely to be under genetic control. In contrast to courtship or feeding behaviors, it was shown in laboratory rodents that genetic variants explained on average under 10% of the variation in behaviors related to locomotion, addiction, or emotions in different test situations (Flint 2003).

The genetic architecture of animal behavior consists of different genetic components. Genetic variation of behavior is referred to as additive when deviations from the mean behavior phenotype are caused by a specific genetic variant A (allele A) or variant B (allele B) and the combination of both alleles (heterozygote genotype AB) results in the intermediate behavior phenotype between the homozygote genotypes AA and BB. If there is a non-additive interaction between the alleles at a given loci, and thus, the heterozygote genotype effect is unequal to the mean phenotype, this is referred to as dominant variance. The third component is the epistatic variance which also described a non-additive interaction between two alleles but in contrast to the dominant variance, at different loci.

Dissecting the genetic architecture of behavior into these three components is rare; most studies report the additive genetic variance. In great tits (*Parus major*), however, additive and non-additive genetic effects on exploration and boldness have been analyzed and dominance effects were identified as major determinant of behavior differences besides additive genetic effects (van Oers et al. 2004).

Another factor that needs to be considered for the dissection of the genetic architecture of behavior is the genetic correlation. Genetic correlations are the results of either pleiotropy (when one genetic locus affects multiple traits) or less common of linkage (when genetic loci which affect multiple traits are inherited together) and can occur between behavior traits and behavior traits and non-behavior traits. A selection experiment in the Red Junglefowl, which are ancestors of the domestic chicken, demonstrated a genetic

correlation between fear of humans and other behaviors like fearfulness and exploration in other contexts (Agnvall et al. 2012). And even when behavior traits share only little common genetic loci contributing to the behavior variation, the same molecular pathways can be affected by the individual genetic variant and thus a phenotypic correlation is observable (York 2018).

Evidence for a genetic correlation between behavior traits and non-behavior traits is once again delivered by the process of domestication: both the domestication of the dog and the farm fox experiment demonstrate a link between the selection for behavior and morphological traits. In the creation of dog breeds, for example, functionality was closely linked to morphological features. Breeds excelling in hunting behavior often have different skull and body shapes compared to breeds selected for guarding or herding. In a genome-wide association study, genetic variants that were associated with fear or aggression in various contexts were also associated with morphological traits (Zapata et al. 2016). Likewise, Belyaev's farm foxes changed their appearance with progressing selection: depigmentation, brown mottling, grey hairs, shorter legs and tails, and upward curled tails as in dogs occurred in the tame foxes compared to the unselected control group (Trut 1999).

Besides direct genetic effects on behavior within animals, interacting genetic effects between individuals (indirect genetic effects) can occur. Indirect genetic effects describe the phenomenon that the phenotype of an individual is influenced by genetic variations of conspecifics, e.g., maternal effects on the offspring or an individual's adaptation on behaviors of opponents or family members. It is assumed that indirect genetic effects can contribute to the expression of behavior variances in the context of social interactions and may therefore also affect evolutionary dynamics: for example, highly aggressive Mediterranean field crickets (*Gryllus bimaculatus*) reduced aggressive behavior in opponents due to indirect genetic effects and this in turn reduced the total genetic variance of aggressiveness for the whole population (Santostefano et al. 2017). Moreover, the indirect genetic effect on the variance of aggressiveness

also affected the non-social trait “exploration” in the Mediterranean field crickets, indicating that indirect genetic effects are an important part of the multivariate genetic architecture of behavior.

## Candidate Mechanisms for Behavior Genetics

Complex physiological structures are involved in receiving, transmitting, and processing information that lead to a behavior response. Genetic variations which affect these structures are the origin of the genetic background of behavior. Variations in the genetic code (single nucleotide polymorphisms, insertions or deletions, structural variants) due to mutations can modulate the expression of genes (gene regulation) and protein structures, and thus complex circuits. Target structures underlying behavior modifications with a genetic component are primarily proteins, hormones, or neurotransmitters themselves affecting complex circuits belonging to the sensory system or neuromodulatory pathways (Bendesky and Bargmann 2011).

At the genetic level, a few strong candidate genes for behavior traits or personality have been described among species that affect the level of neurotransmitters, like the dopamine receptor D4 (*DRD4*), monoamine oxidase A (*MAOA*), and serotonin transporter (*SERT*) genes. Across species, allelic variations in *DRD4* were associated with personality traits like exploratory or novelty-seeking behaviors (Fidler et al. 2007; Garamszegi et al. 2014). Allelic variations in *MAOA* and *SERT*, for example, can alter the enzyme activity and thus affect the neurotransmitter levels, which was linked to aggressive behavior in different species (Sacco et al. 2017; Wendland et al. 2006).

It is assumed that proteins involved in modulating behaviors have general functions, like protein kinases, e.g., the cGMP-dependent protein kinase (PKG). Genetic variations that affect PKG activity are described to mediate various behaviors across multiple species, e.g., foraging in *Drosophila melanogaster*, circadian rhythmicity in rats, and addiction and anxiety in mice

(reviewed in Reaume and Sokolowski 2009). Genetic variations in G-protein-coupled neurotransmitter receptors (GPCR) and their regulators (*Rgs2*, *Avpr1a*, *tyra-3*, *npr-1*) are also associated with behavior traits in several animals of which all have in common that the animals internal state is affected by the GPCR system (Bendesky and Bargmann 2011).

Candidate hormones, especially in regard to social interactions like paternal care, are oxytocin and vasopressin. Oxytocin is a neuropeptide released by the hypothalamus that acts in the brain and it affects the reproductive system but also behaviors related to social bonding. Vasopressin, likewise, is produced in the hypothalamus and modulates stress response-related behaviors (fight or flight). Its effects are often antagonistic to oxytocin and therefore it is considered as oxytocin’s counterpart.

Considering complex circuits that play a role in the biological background of behavior, the hypothalamus itself is part of the hypothalamic-pituitary-adrenocortical (HPA) axis, a system that is involved in the physiological response to stress and thus can mediate behavior as well. For example the corticotrophin-releasing hormone is a major modulator of the HPA axis and changes in the expression of corticotrophin-releasing hormone receptor genes were shown to affect the susceptibility to stress and anxiety behavior in mice (Bale et al. 2000).

## Assessing the Genetic Background of Animal Behavior

### Determining the Behavior Phenotype

In the era of high-throughput genotyping methods, determining a suitable phenotype is key for the success of association studies. This is especially true for complex behavior traits as they are often confounded with each other and there are multiple ways of measuring them. Important features of suitable behavior phenotypes are (I) an easy recording and (II) a clear characterization under the consideration of environmental factors. An easy recording of behavior phenotypes is crucial because generally, large sample sizes are

needed for genetic studies and labor, time and space intensive methods of behavior recording would interfere with that. A clear characterization of behavior traits and appropriate methods to measure the target trait under the consideration of environmental factors are important to control for confounded traits and environmental variation. However, some behaviors are often interwoven with each other, which hinders a separate consideration, e.g., a separate dissection of fearful and aggressive reactions in challenging situations is difficult because aggression can be a consequence of fear (fight or flight response).

Generally, the above-described features can be better accounted for in experimental settings using behavior tests compared to field studies which normally include intensive observations. Common behavior tests in experimental settings for laboratory animals like rodents are the open-field test or the elevated plus maze test and their variations (e.g., the novel-object test). The open-field test comprises behavior records when animals are exposed to an (unknown) arena, and it is supposed to measure behavior traits like fear, novelty, or risk seeking and exploratory behavior. Typical measures are time spend close to the walls or in certain sections of the field, time being active or inactive, frequency of urination or when an object is placed in the open-field (novel-object test), the frequency and duration of animal-object contact. The elevated plus maze test is a plus-shaped runway with two arms enclosed and the others open and is usually used to characterize anxiety in rodents by measuring the time animals spend in the different types of arms.

Methods like the open-field test can also be applied to larger model animals or livestock species. In the case of livestock species, however, the behavior trait of interest, e.g., for genomic selection, is often temperament in response to human handling or contact. Therefore, behaviors in the presence of humans are measured, either in test situations (e.g., flight-speed or novel-human test) or in everyday handling situations (e.g. milking, weaning, regrouping or weighting). In test situations, objective measurements like the speed when leaving a chute (flight-speed test) or frequency of human-animal contact (novel-human

test) can be elaborated to characterize temperament whereas in handling situations, temperament scores are normally given by handlers, and therefore they might be subjected to a certain subjectivity.

Subjectivity is also one of the limitations when behaviors, especially personality, are assessed via owner-questionnaires which is a common method in pets. For example, the Canine Behavioral Assessment & Research Questionnaire (C-BARQ) is frequently used for the behavior phenotyping in genetic studies of dogs (Zapata et al. 2016). As advantages, questionnaires are a useful tool to acquire large sample sizes and assess every-day behaviors that are not biased by a test setting.

Sometimes however, experimental settings are not appropriate to phenotype behavior. This is the case when the target behavior cannot be replicated in the laboratory or under captivity, e.g., mating or nesting behaviors and habitat choice, or when the animals of interest are wild species (Merrick and Koprowski 2017). Observations can be automated, for example, tracking methods for social interactions, but manual observations remain important techniques for characterizing behavior variations in wild animals.

## Genetic Analyses

When the extent to which genetic variants contribute to behavior differences between individuals is of interest, heritabilities can be estimated. Heritability estimates are calculated based on observations for related individuals by partitioning the behavior differences to a genetic, an environmental, and a residual (error) component. Relationship information can be assessed from pedigrees or from genotypes, which is especially valuable in wild populations. Generally, heritability estimates for behavior or personality traits tend to be low or moderate, with only a few exceptions of traits with a high heritability (York 2018).

Besides heritability estimates for behavior traits, specific genetic variants underlying behavior differences and their effects can be identified. Before specific genes and their variants that underlie behavioral differences can be identified, a genome-wide scan is normally conducted to localize genomic regions (quantitative trait loci;

QTL) that are associated with the behavior trait (QTL study or association mapping). To achieve this, one utilizes the circumstance that a genetic variant, which is often referred to as genetic marker in these studies, is either the causative mutation itself which is associated with the behavior trait or is in close distance to the causative mutation and thus they are inherited together. Prerequisites for these genome-wide scans are genetic variants, either SNPs or microsatellites, that are distributed across the genome and for which animals can be genotyped by SNP genotype array technologies or by whole-genome sequencing (WGS). The genotyping technology affects the resolution of the genotype information available for the QTL mapping or association study: whereas SNP genotype arrays meanwhile cover hundreds of thousands of loci for most animals, WGS provides an even more complex picture.

The availability of genetic markers (type and number), the structure of the population under analysis, and the scientific objective determine which genetic method is suitable to analyze the genetic background of behavior. For linkage mapping, which can be applied in related individuals, the genetic distance between markers is utilized. Therefore, a genetic map (or linkage map) is calculated first, which describes the frequency of recombination between two markers. The following principle applies: The further away two markers are from each other, the higher is the likelihood that they are inherited independently from each other, or in other words, the higher is the recombination rate and thus the genetic distance. Information on the linkage map can be used to map QTL (QTL mapping) assuming that markers and causative mutations that are linked to the behavior variation segregate together in related individuals. Favorably intercrosses or backcrosses of strains which show a high variability of the trait of interest are used for these studies. Laboratory rodents as mice and rats are predominant animals for QTL mapping studies (Flint 2003) due to the availability of inbred strains, short generation intervals, and the high number of offspring. Another advantage of laboratory animals for QTL mapping studies is the fact that the

environment can be standardized for all individuals to minimize interactions between genes and the environment and variations due to environmental influences.

QTL mapping is a useful tool to determine genomic regions associated with the behavior trait of interest. However, the application of QTL mapping is not only limited to assess general insights into behavior genetics using experimental populations, it can also be used to identify candidate genes with strong effects on the behavior phenotype. In accordance, QTL mapping was successfully applied to tackle behavior conditions in livestock species, e.g., the porcine stress syndrome (PSS) in pigs. PSS is an inherited condition that causes pigs to have severe muscle contraction, hypermetabolism, and an elevation in body temperature when inhaled anesthetics or when exposed to environmental stress. With QTL mapping, the swine stress gene (*hal*) was identified on chromosome 6 because variants in this gene were associated with PSS (Davies et al. 1988).

Pinpointing associations to specific genetic loci is the underlying objective of genome-wide association studies (GWAS). In contrast to QTL mapping studies, GWAS use the actual physiological positions of genetic markers to identify QTL and study objects can be unrelated individuals making GWAS an ideal tool for analyzing behavior in wild populations with unknown pedigree. The underlying principle of a GWAS is the linkage disequilibrium (LD) that exists for genomic regions. If LD and the genetic marker (SNPs) distribution are sufficient, genetic markers and causative mutations are linked to each other and an association can be found between allele frequencies and behavior variations. In unrelated animals, much more crossing-over has occurred, decreasing the LD and thus requiring a higher coverage of genetic markers. GWAS have higher power to detect QTL with small effects compared to QTL mapping studies, which might be useful for the dissection of the genetic architecture of behavior in animals. Accordingly, GWAS have significantly contributed to the dissection of the genetic architecture of behavior, for example, strong candidate genes for feeding behavior and eating efficiency in pigs were identified (Do et al. 2013).

Pinpointing the causal variation, however, often requires a fine-mapping of the identified genomic region associated with the behavior trait. Therefore, instead of scanning the whole genome, single genes can be explored for associations with behavior variation: the genotyping can be limited to candidate genes for association studies or functional analyses of candidate genes can be conducted. Candidate genes can be determined either by using the genes harbored by QTL identified in other studies (positional candidates) or based on their known function in pathways that modulate behavior (functional candidates). Based on what can be learned from laboratory rodent studies, regions of DNA should be appropriately prioritized to find the molecular variants, for instance by looking at sequences that control the level of gene expression rather than variants in coding regions (Flint 2003).

The first mapped candidate gene for behavior which is conserved across species is the foraging gene *for*. The *for* gene codes for the cGMP-dependent protein kinase (PKG) and variants in the *for* gene were linked to foraging behavior in *Drosophila melanogaster* first, but over the years, a similar function in multiple other species was described in studies using *for* as functional candidate gene (Fitzpatrick et al. 2005).

Once the positional or functional candidate gene is recognized, the causal variants can be identified and verified by linking genotypes with trait variation or by generating knock-out strains and comparing the behavior of the knock-out strain with the wild type. A recent genome editing technique for the creation of knock-out models is the CRISPR-Cas9 approach. Briefly, this approach works as following: Directed by a specific RNA which binds at the target sequence in the genome and to the Cas9 enzyme, the Cas9 enzyme cuts at the target DNA sequence and the own repair mechanism of the cell can be used subsequently to modify the DNA sequence by adding, removing, or replacing specific segments. This approach of creating knock-out animal models has been demonstrated to be useful in the analysis of genetic variations with a strong effect on the behavior phenotype (Lee et al. 2018).

For future studies on the genetic background of animal behavior, the combination of high-throughput genotyping methods like WGS and the use of animal models created with precise genome editing methods like the CRISPR-Cas9 approach will largely contribute to a better understanding of the genetic architecture of behavior (York 2018).

## Genetic Background of Specific Behaviors

Behavior comprises single traits to complex patterns, and all of them can show intra- and inter-species variation: some behaviors are conserved across species, like general behaviors as aggression and fear, while other more specific behaviors are only expressed exclusively in certain species, e.g., communication patterns like a courtship song only observed in *Drosophila melanogaster* or pointing behavior in some dog breeds. This inter- and intra-specific variation of behaviors is also manifested in the genetic background.

Regardless of the type of variation (inter- or intra-species), behaviors that have a strong influence on an individual's fitness are more likely to be under genetic control. Such behaviors are normally related to reproductive success (e.g., maternal or mating behavior) and survival (e.g., adaptation or hunting behavior).

Social interactions comprise some of these evolutionary relevant traits (maternal care, mating choice, and affiliative or aggressive interactions between individuals) and are therefore often analyzed for their genetic background. Maternal behaviors, for example, include parenting skills like nest building, cleaning and feeding, or social interaction (communication and recognition) with the offspring. For the latter, genetic variants, which affect the level of hormones like oxytocin, have turned out to be a target mechanism. Assessing and evaluating the genetic background of maternal behavior is especially relevant in livestock species, because maternal behavior affects the survival of the offspring and thus the productivity. For example, in sows, behavioral reactions towards human handling and towards screams of

the piglets were genetically correlated with the survival of the offspring indicating the possibility of genomic selection for behavioral traits in livestock species (Grandinson et al. 2003).

Considering variations in social interactions between conspecifics, which can among others be characterized by aggressiveness or affiliation, an individual's adaptation ability on changing environments is one of the major modulators. Again, this is especially relevant and therefore frequently analyzed in livestock species, where regular regroupings or handling situations require substantial resilience to stress. For example, an animal's failure to cope with this stress can lead to an increased aggressiveness towards conspecifics or littermates and in the worst case, affect the fitness of the entire population or group. For stress reactivity, genetic variants that influence the activity of the HPA axis play a crucial role (Muráni et al. 2010).

Another central aspect of social interactions between animals of the same species that influence a wide variety of behaviors relevant for the individual fitness, e.g., mating behavior, can be attributed to communication abilities. Accordingly an effect of genetic variants on communication skills has been shown, e.g. variants in the *period* gene that affected courtship songs and thus mating in *Drosophila melanogaster* (Wheeler et al. 1991).

The *period* gene is also a classical and well-studied example for the genetics of circadian behaviors in animals. Interestingly, the genetic background of circadian behaviors in model species like *Drosophila melanogaster* can be transferred to behavior genetics in humans (Toh et al. 2001) and thus indicates the relevance of animal behavior genetics for human behavior. Therefore, behavior genetics in animals often serve as prerequisites for behavior genetics of conditions like addiction or psychiatric disorders in humans. To study the genetics of addiction to specific substances like drugs, alcohol, or tobacco, genetic analyses are frequently performed using mouse models: in mice, variants in *nAChR* subunit genes were linked to the behavioral effects of nicotine and nicotine addiction or *GABA* genes to alcohol and other addictions and provided

valuable insights into general mechanisms of addiction that can be used in humans (Li and Burmeister 2009). Knock-out mice exposed to stressful situations can give insights into the background of mood-related behaviors and are also valuable models for the analysis of psychiatric disorders like anxiety and depression in humans (Cryan and Holmes 2005).

A specific interest exists in the genetic background of animal personality. "Personality," "temperament" or "behavior syndrome" comprises the pattern of a wide range of behavior traits like fear, aggression, or social interaction of which variations that are relatively stable across situations are characteristics for an individual (Sih et al. 2004). For example, some animals tend to be more aggressive or bold in various circumstances in contrast to others. Personality can be assessed for a variety of species and is assumed to have a genetic background, because these individual characteristics (or reaction norms) lead to different fitness abilities across environments (Penke et al. 2007) and might therefore affect natural selection in an ecological or evolutionary context. In accordance, genetic studies have shown a heritable component of different aspects of personality (e.g., aggression, boldness, risk-taking) in different species (e.g., sticklebacks, great tits, chimpanzees, dogs, and sheep) ranging from 0.01 to 0.66 (van Oers et al. 2005). However, compared to evolutionary more important behavior traits like courtship, personality variations are less attributable to a genetic control (York 2018).

## Interactions Between Genes and Environment

As addressed in the nature vs. nurture debate, behavior has a genetic and a non-genetic (environmental) component. The effect proportion of both components on behavior variation usually depends on the behavior trait or pattern itself. Generally, it is assumed that most behaviors are to a greater extent affected by the environment and just a few behaviors, e.g., courtship, have a moderate to strong genetic background. Some of

the environmental factors that can affect behavior in animals are weather conditions, the feed availability, the presence of other animals, and individual experiences. Environmental factors can modulate individual behavior throughout the whole lifespan, whereas the genetic predisposition is fixed: The genetic predisposition defines the reaction norm (range) in which behavior variations in the sense of adaptation can occur when the environmental situation changes. The relationship between genetic and environmental components is not necessarily linear (in the sense that an individual carrying a specific variant is always superior across environments), but they can interact with each other. This interaction between genes and environment can result in different reaction norms and thus in different preferences of genotypes over environmental influences. For example, a specific genetic variant 1 in a gene can cause bold behavior in an environment A and a genetic variant 2 in the same gene can also cause boldness, but only under the conditions of environment B (van Oers et al. 2005). This interaction is especially interesting from an evolutionary point of view of behavior: Assessing the genetic predisposition for specific behavioral traits in wild populations and the genetic correlation between these traits and environmental conditions can give insights into behavioral adaptation to changing environments in the course of evolution (Atwell et al. 2012).

In the analysis of interactions between genes and environment that affect behavior variation at the population and the individual level, behavioral plasticity plays a central role. Plasticity describes the within-individual adaptive abilities to environmental changes within the reaction norms provided by the genetic predisposition. Analyzing the genetic background of behavioral plasticity can also give insights into consistency and stability of behavioral traits or patterns, e.g., personality, across situations, and over time (Dingemanse et al. 2012).

But how exactly do genetic and environmental factors interact with or influence each other and thus affect adaptation abilities in animals? On the genetic side, genetic variants can determine how environmental cues are received, transmitted, and

processed, for example, by modifying mechanisms of the sensory system, such as chemoreceptors or sensory organs like eyes and ears. In this case, even if animals receive the same environmental cues, some can be more susceptible than others due to a predisposed higher sensitivity. Then, experiences play a crucial role in the development of different behaviors in individuals and genetic variants can affect how these experiences are processed and stored through modulating the memory and learning abilities. Environmental factors themselves can influence the inner state of an individual, e.g., increased hunger through reduced feed availability, and thus, affect biological mechanisms like gene expression and hormonal levels.

## Conclusions

Dissecting the genetic architecture of behavior in animals includes some caveats that need to be addressed, but once these challenges are overcome, animal behavior genetics can provide valuable information in an evolutionary, an animal welfare and a human genetics, context.

One of the major challenges in the analysis of behavior genetics is the phenotype itself. Caveats are that many behaviors are correlated, e.g., fear and aggression considering the fight or flight response, and that the trait distribution is most of the times unsuitable for statistical models, which often require normally distributed traits. Therefore, the behavior trait or pattern needs to be defined carefully and tested for correlations and data transformation might be considered. For example, instead of measuring the frequency of urination in a fear test in rodents, where probably just a few animals show the trait at all, transforming the trait “urination” into a binary trait (urination yes or no) can avoid a skewed distribution and can be analyzed with the appropriate statistical model.

Second, sometimes only subjective scores exist, e.g., for temperament in cattle, instead of “measurable” behavior traits, which can introduce bias when the scoring was performed by different observers. To address this problem, it can be

helpful to dissect complex behaviors to measurable sequences: for example, break down “maternal behavior” to the time the mother spends feeding and grooming the offspring. And third, genetic studies require a large sample size which is difficult to achieve with a complex, i.e., time intensive, behavior observation or testing.

However, there is a growing interest in the genetic dissection of behavior in animals regarding putative applications (genomic selection for behavior) and basic research (evolution and human behavior genetics). Selecting for behavior is especially relevant in domesticated species, as livestock and companion animals. The possibility to select for favorable behavior traits like tameness and reduced aggression towards humans or stress resistance (adaptation to changing environments) can affect both the animal’s welfare and the welfare of the handler or owner. Finally, generating insights into the genetic background of animal behavior might help to tackle behavioral and psychological disorders in humans by identifying new candidate genes and thus involved physiological pathways that can be targeted by medications.

## Synonyms

Gene; Genetics; Omics

## Definition

The influence of gene expression on behavior.

## Introduction

The diversity of behavior across the animal kingdom, including both invertebrate and vertebrate classes, is vast, complex, and is not always predictable or easily explained by physiological makeup (Harris and Hofmann 2014). Nature versus nurture debates have been long standing; however, since the development of genomic analysis, it has become apparent that there is a relationship of environmental impact on physiological and behavioral phenotypes, inextricably linking nature and nurture together in the phenotypic expression of diverse behaviors (Hofmann 2003).

The primary constituents of deoxyribonucleic acid (DNA) are four nucleic acids: adenine (A), guanine (G), thymine (T), and cytosine (C) arranged in a double helix. Sections of DNA of a specific order, called genes, are hereditary and some encode for proteins that form and maintain cellular components and processes throughout an organism. Genes are either active or silent, and vary depending on hereditary succession. Gene regulatory expression can be modified, however, especially during developmental periods, by events such as toxin exposure, malnutrition, or hypoxia (Khurana et al. 2019; Lalonde et al. 2020;

Murray et al. 2020). These events lead to changes in offspring that can often be heritable – known as epigenetic modification. Other behavioral differences can occur through chromosomal or gene mutations and deletions that lead to permanent changes in the DNA sequence. The advance of molecular technology used to study modifications, mutations, and heritable status of the genome has expanded scientific understanding and exploration of different aspects of animal behavior, such as cognition, social interactions, and pathologies.

## Cognition

Often defined as the ability to acquire and process new knowledge, cognition involves experiential learning, perception, short- and long-term memory, evaluation, and decision making. Cognition in animals with neural complexity comprises multiple brain regions and neural pathways. Normal cognitive function is important in an animal's success, which, on a basic level, is survival and reproduction.

Epigenetic regulation of parental alleles, variants of a gene, can lead to monoallelic expression or co-expression providing a refined modulatory effect on neural networks (Ho-Shing and Dulac 2019). Use of novel high throughput molecular technology such as Next Generation Sequencing (NGS) can reveal DNA sequences including abnormalities and variations such as copy number variants, deletions, and insertions. Investigation of brain regions at various stages of development using NGS implicates stage-specific and region-specific sensitivity of gene regulation in the brain (Ho-Shing and Dulac 2019).

The functionality of synaptic transmission and plasticity – fundamental processes to multiple aspects of cognition – relies on proper cellular operation and maintenance. Deletion of maternally expressed genes can change neuronal firing patterns, vesicle turnover rates, as well as long-term depression and potentiation (Ho-Shing and Dulac 2019; Jiao and Li 2011; Sun et al. 2015; Wallace et al. 2017). Expression changes in the genes involved in these processes have been linked to memory deficits and interrupted sleep

patterns in mice and is directly associated to Birk-Barel Intellectual Disability Syndrome as evidenced by the rescue of the phenotype with paternal alleles of the gene (Cooper et al. 2020; Gotter et al. 2011; Ho-Shing and Dulac 2019).

With chromosomal microarray analysis, a process that detects deletions and additions by comparing genomic data to a normal control, behavioral phenotypes with impaired cognition show copy number variants present in a specific gene, *CHRNA7* (Gillentine et al. 2017). Duplication of *CHRNA7*, a gene that encodes for a subunit of a neuronal nicotinic acetylcholine receptor, is related to intellectual deficits, autism spectrum disorder, and attention deficit hyperactivity disorder (Gillentine et al. 2017).

Normal cognitive variation is also heavily attributed to genetic expression, which is influenced by the environment (Tucker-Drob et al. 2013). Enriched environments promote increased learning and memory function in rodents, as well as increased genetic expression in genes responsible for synaptic transmission and plasticity (Rampon et al. 2000). Environmental enrichment alters cognitive abilities sufficiently such that substantial research is focused on ameliorating disorders by using it as a treatment, such as in Alzheimer's disease, which presents with cognitive decline and memory loss (Griñán-Ferré et al. 2018; Jake Rogers et al. 2019).

Developmental plasticity through environmental exposure can lead to a variety of adaptive and maladaptive cognitive phenotypes (Lafuente and Beldade 2019). Behavioral modifications through context-dependent genetic expression, induced by the environment, may be heritable and occur through a myriad of multifaceted processes such as histone acetylation, methylation of CpG islands on gene promotor regions, and microRNA regulation. The end results are a change in differential expression and a downstream effect on cellular functioning and neural networks. The changes in cognitive abilities can vary depending on the species and the stage of development. Further to cognitive function, social behavior is an important aspect of animal behavior and is subject to genetic influence.

## Social Interactions

Social interaction is not a significant component of all animal classes, but it is pertinent for many, especially in nonhuman primates (Sueur and Mery 2017). Social interactions influence group hierarchy, learning, and mating success (Kurvers et al. 2014; Senior et al. 2016; Silk et al. 2003; Sueur and Mery 2017).

Hierarchy in some social groups leads to increased mating success and preference as well as preferred resource allocation. Inherited phenotypes can lead to offspring dominance succession; however, candidate genes for social dominance have not been replicable in other studies (van der Kooij and Sandi 2015). Relatable traits for aggression and reward behavior, however, have been associated with social rank in offspring (van der Kooij and Sandi 2015).

When presented with a novel conspecific, vervet monkey reactions to the strangers were recorded and analyzed, showing variability in aggression that was associated with genetic differences (Jeffrey Rogers 2018). Analysis of grooming behavior in chimpanzees has shown variations in the arginine vasopressin receptor gene, *AVPR1A* (Jeffrey Rogers 2018). Increasingly, multiple studies are producing similar results, providing further evidence of a genetic component to social behavior in animals.

Adaptive cognition and social interaction have implications for survival and fitness; however, genetics can also influence deleterious diseases and disorders.

## Pathology

Predominantly, animal research into behavioral pathology focuses on human-comparative animal models and are often not wild, free range expressed behaviors; however, some researchers have begun implementing tasks devised to enhance animal participation rather than forced manipulation (Spanagel 2017). Early research in the 2000s began to link genetics as a putative factor in psychiatric disorders (Inoue and Lupski 2003). Technology quickly advanced over the next two decades

and led to sincere developments in genetic predispositions and foundations for a number of disorders such as schizophrenia, bipolar disorder, major depressive disorder, and addictions (Maldonado et al. 2021; O'Donovan and Owen 2016).

Increased expression in regulatory genes in the ventral tegmental area and a decrease in DNA methylation within the prefrontal cortex of rodent animal models have been associated with food addictive behaviors (Maldonado et al. 2021). Substance abuse addictive behaviors are also explored using animal models, including transgenic mutant models, whereby researchers utilize gene editing, such as CRISPR/Cas9, to modify a gene of interest by insertion or silencing (Spanagel 2017).

Contextually-inappropriate aggression has been linked to attention deficit hyperactivity disorder, schizophrenia, and bipolar disorders and is another focus of human-comparative animal studies (Zhang-James et al. 2019). Excessive aggression and violence are maladaptive behaviors modeled in feral animal studies that have illuminated serotonin signal malfunction through receptors (de Boer 2018). A large, integrated analysis of the human genome; animal transcriptomes from mice, rats, zebrafish, and *Drosophila*; and genetic knock-out studies has linked aggression to functional gene pathways common to both humans and animals, leading to putative targets for further research in psychiatric disorders (Zhang-James et al. 2019).

Anxiety can lead to inhibition, indecisiveness, and retreat of social interactions. For some animals, inhibition and reluctance to explore can be a protective mechanism and increase chances of survival; however, it could also lead to loss of opportunity for food and potential mates. Anxiety disorders in humans are common and research on animal models is abundant (Purves et al. 2020; Schiele and Domschke 2018). Serotonergic and methyltransferase genes are among the list of putative targets for treatment of anxiety disorders (Gottschalk and Domschke 2017). Some evidence has also linked single nucleotide polymorphisms (SNP), which is a gene with a substituted nucleotide, to anxiety; however, the combined efforts of genetic research currently does not account for the heritability of anxiety disorders, leading

researchers to turn to epigenetic modifications (Schiele and Domschke 2018).

## Relevance to Understanding Human Behavior

Often, animal models aim to glean information that might ultimately be relevant to human phenotypes. The study of behavioral genomics is longstanding in human models as well, beginning with Sir Francis Galton, who studied twins who varied in reported similarity to ascertain the extent to which individual differences in some traits, such as intelligence, appear heritable. He suggested that similar twins remained similar as they aged, even if they were raised in different environments. This approach led Galton to conclude that genetics is a major determinant of human behavior (Galton 1875). Today, research has highlighted the role of genetics in accounting for upward of 20–50% of variance in human intelligence (Plomin and Von Stumm 2018). Researchers now recognize the role of gene x environment interactions in shaping psychology and behavior. For example, Caspi et al. (2002) showed that adverse effects of childhood maltreatment in terms of manifestation of conduct disorder were strongest among children who also exhibited low monoamine oxidase (MAOA) activity via a functional polymorphism in the gene encoding for MAOA. Other research has demonstrated that individuals exposed to stressful life circumstances are more likely to experience depression and suicidality if they also have a short allele in the promoter region of the serotonin transporter (5-HTT) gene relative to those who were homozygous for the long allele (Caspi et al. 2003). Today, the diminishing cost of genomic sequencing has made the field more accessible, leading some to describe behavioral genetics as a postgraduate growth area in the field of psychology (Willyard 2010).

## Conclusion

Animal behavior is complex and variable across species, sexes, and stages of development. Within

each of those categories, there is significant variability in many behavior phenotypes including but not limited to cognition, social interaction, aggression, and anxiety which appear to be best predicted by consideration of both genetic and environmental factors. Modification of gene expression can occur via different intricate processes influenced by the environment and by parental inheritance that can be linked to variability in animal psychology and behavior.

## Behavioral Levels

Gary Greenberg

Wichita State University, Wichita, KS, USA

The contemporary model of development, relational developmental systems (Overton and Lerner 2014), is very much grounded in Darwinian evolution, but not the modern synthesis of this position. One can understand the important role that ideas of evolution play in behavioral development without adopting a reductionist, determinist, or otherwise innate perspective (Lerner and Overton 2013; Lickliter 2016). Behavior develops and changes, a result of a myriad of influences (endogenous and exogenous) almost from the moment of conception and, based on current understanding of epigenetics (e.g., Moore 2015, 2016), perhaps before as well. Evolution, of course, is itself about change, and therein lies the crucial relationship between biology and psychology.

The fundamental law of Darwinian evolution is that change results from *natural selection*. But, as with all theories in science, Darwinian evolution has itself been subject to change and modernization. Accordingly, I follow Ho and Saunders in understanding *increasing complexity* (i.e., anagenesis) to be a second law of evolution after natural selection (Saunders and Ho 1976, 1981). Others who have adopted this line of thinking (e.g., Stebbins 1969; Smith and Szathmáry 1995) did so from the perspective of the idea that there is a hierarchy of levels of increasing complexity and organization with evolution. Indeed, this idea can be considered “a central phenomenon of life” (Vrba and Eldredge 1984, p. 146). That this principle is extremely important in scientific understanding was recognized early by Pringle (1951) who noted that “The characteristic of living systems which distinguishes them most clearly from the non-living is their property of progressing by the process which is called evolution from less to more complex states of organization” (p. 175).

This hierarchical principle applies as well to the sciences which can be divided into areas of study based on qualitative changes in complexity of organization: physics and chemistry address lower levels of complexity; biology, psychology, and sociology address higher levels of complexity. This idea appears to have originated with Auguste Comte in the late 1800s (see Boorstein 1998, p. 223) and was subsequently developed in the twentieth century by others such as Novikoff (1945) and Feibleman (1954) (Greenberg and Partridge 2010; Greenberg and Tobach 1984), conceptualized as the “concept of integrative levels.” Aronson (1984) described this idea as a crucial organizing principle in science which is “... a view of the universe as a family of hierarchies in which natural phenomena exist in levels of increasing organization and complexity. Associated with this concept is the important corollary that these successions of levels are the products of evolution. Herein lies the parallel with anagenesis” (p. 66).

In their important book, Michel and Moore (1995) noted that T. C. Schneirla, among the pre-eminent comparative psychologists of the twentieth century, applied this thinking to behavior invoking the idea of phyletic levels. Michel and Moore note that by advancing “the idea that the study of evolution could be informed by developmental analysis” (p. 120) Schneirla emphasized that both biology and psychology are developmental sciences. The historical record is clear that as evolution has continued it has resulted in increasingly more complex forms of animal life. In the context of this discussion it is evident that, with few exceptions, more recently evolved forms are more complex in their biology and their behavior than are earlier evolved forms. Schneirla pointed out that we can “begin to understand the differences between species by noting gross differences in behavioral complexity” (Michel and Moore 1995, p. 121) in a hierarchical relationship reflecting a strong correlation between both biological and psychological complexity.

Applying this idea to behavior, Tobach and Schneirla (1968) proposed an anagenetic, hierarchical ranking of behavioral levels across species,

based loosely on the fact of increasing neural complexity with evolutionary advance. The behavioral levels are separated into two groups, one at which biological factors dominate behavior and one at which psychological and social principles become important. The levels they identified are: *Taxis*, at which behavior is under immediate stimulus control, an example of which is a moth flying toward a light source; *Biotaxis*, a higher level at which behavior is influenced not only by the immediate presence of a stimulus but also by the presence of biochemical sequelae from other organisms such as pheromones; and *Biosocial*, the level at which the social interaction of groups of animals plays an important role in organizing and regulating behavior. In Schneirla’s analysis of army ant behavior, he saw their cyclic activity to be a result of reciprocal social stimulation provided by the enormous number of individuals in an ant colony. That cyclic activity is absent in single ants and is seen only when ants are together in large numbers; *Psychotaxis*: Psychology becomes important at this phyletic level in the form of mediation by past experience. Rosenblatt and Schneirla (1962) demonstrated with cats that the relationship between infant and mother begins with biotactic orientation by the kitten to its mother by means of tactile and olfactory stimuli. Subsequently, higher-order processes (e.g., learning and reinforcement) enter in at later stages of that relationship; *Psychosocial*: at this highest level behavioral organization is regulated by complex social bonds and social interactions characteristic of advanced vertebrates. Among primates, for example, lasting social bonds result from initial complex biosocial and biotactic interactions between an infant and a mother such as those involved in rocking, providing of contact comfort, and nursing.

Tobach and Schneirla (1968) ended their analysis with the description of the psychosocial level. There is, however, merit in developing the system somewhat further to differentiate among phyletic levels of primates and their corresponding communication behaviors. Whereas the behavior of all primates falls into the psychosocial level, at least with respect to communication there are less and

more complex forms. All primates communicate, but a few individuals of some species have developed complex communication skills, bordering on true language (Savage-Rumbaugh et al. 1993). Accordingly, it seems appropriate to further subdivide the psychosocial level into three separate behavioral sub-groupings (Psychosocial I, II, and III; Greenberg and Haraway 2002), distinguished by the nature of communication complexity: a communication only, nonlanguage level (e.g., vervet monkeys); a proto-language level (e.g., chimpanzees and bonobos); and a true language level (only *H. sapiens*). Each of these behavioral levels is demarcated by the evolutionary appearance of species whose behavioral repertoires are increasingly more plastic and complex (Lerner 1984) as are their nervous systems. This ordering of these levels is similar to that of traditional phylogenetic taxonomies.

The utility of the application of this behavioral taxonomy can be seen in the way Greenberg and Haraway (2002) demonstrated its use for feeding behavior and its complexity across phyla and species. As animals became more complex with evolutionary advance, their nervous systems and feeding behavior became increasingly diverse and flexible. Table 1 lists major animal groups and shows at which behavioral (phyletic) levels their feeding behavior may be organized.

**Behavioral Levels, Table 1** Levels of behavioral complexity displayed by major animal groups in feeding behavior

| Major groups           | Higher levels of complexity illustrated |
|------------------------|-----------------------------------------|
| <i>Protozoa</i>        | Taxic                                   |
| <i>Cnidaria</i>        | Taxic                                   |
| <i>Cnidaria</i>        | Biotaxic, biosocial                     |
| <i>Echinodermata</i>   | Biotaxic, biosocial                     |
| <i>Platyhelmenthes</i> | Biotaxic, psychotaxic                   |
| <i>Molusca</i>         | Biosocial, psychotaxic                  |
| <i>Arthropoda</i>      | Biosocial, psychotaxic                  |
| <i>Osteichthyes</i>    | Biosocial, psychotaxic                  |
| <i>Amphibia</i>        | Biosocial, psychotaxic                  |
| <i>Reptilia</i>        | Biosocial, psychotaxic                  |
| <i>Aves</i>            | Psychotaxic, psychosocial               |
| <i>Mammalia</i>        | Psychotaxic, psychosocial               |

This notion is directed at the classification of behavior. Note that for most groups feeding behavior is organized at more than one level and that individual species can function behaviorally at more than one level (for example, at different stages in its development). Each animal then should be classified at its highest level of behavioral complexity in respect to a behavior, with the idea that a higher classification subsumes the levels below it. In Protozoa, such as the ameba, feeding is regulated solely by the presence of appropriate chemicals at appropriate intensities; they are thus organized taxically for this behavior. Among the Cnidaria, such as Hydra, feeding is mostly a taxic process, although the ability of these animals to distinguish among living or recently living foodstuffs for prey suggests some biotaxic organization. Feeding by mollusks shows even higher organizational processes at work, allowing learning to become an influence of their feeding behavior. Among the vertebrates, feeding complexity, the influence of conspecifics, and many components of learning (e.g., the remarkable caching ability of some birds) show their feeding behaviors to be organized at the highest levels. This organizational system was applied by Greenberg and Haraway (2002) to a full range of behaviors further attesting to its utility and is shown in Table 1.

The heuristic value of Schneirla's use of the levels concept in this way can be seen in replies to criticisms that have been leveled against it (Tobach and Greenberg 1984). Against hereditarianism, the concept poses the question about how genes might function at different levels; there is no special value placed on any level, succeeding levels integrate preceding ones, and the formulation of a question determines the appropriate level of inquiry; the concept does not imply anything about the "proper" research to be done as investigations are needed at all levels; the levels concept provides for the generation of critical hypotheses, especially regarding developmental issues; and finally, "the levels concept . . . belongs to the province of the science historian" (Tobach and Greenberg 1984, p. 6) which is reflected in the statements of Pringle and Aronson cited earlier in this entry.

## Behavioral Stochasticity

Greg Jensen  
Columbia University, New York, NY, USA

“Behavioral stochasticity” is a term that is used to characterize the randomness or apparent indeterminacy of behavior. To call behavior “stochastic” implies more than an observer’s ignorance about the behavior’s provenance. Instead, it implies that the behavior is either deliberately unpredictable or else is fundamentally unstructured. Hereafter, “stochastic” and “random” will be used interchangeably. A lack of behavioral stochasticity, by contrast, is called behavioral stereotypy. Some caution is needed in interpreting these terms when they appear in the literature, particularly “random,” which has a wide range of technical meanings (Nickerson 2002).

Among scholars of animal cognition, there are at least two senses in which behavioral stochasticity is invoked. The first is as a measure of the residual variability of all behavior. The second is as a deliberate strategy or beneficial adaptation. The boundaries between these senses are ambiguous, as behavior may be unpredictable for many reasons. Additionally, behavior that may look very structured on a large scale may simultaneously look unstructured at a small scale (or vice versa), so it is important to specify one’s level of analysis (Shimp 2014).

## Measure of Behavioral Variability

Often, stochasticity refers to the intrinsic variability of the behavior of organisms, such as variations in reaction time or motor plan. As such, a single behavior may have both a predictable and an unpredictable component: A deliberate reaching motion may successfully make contact with a target, but each successful reaching motion varies slightly from previous attempts. Because all behavior varies for a multitude of reasons, many of which cannot be measured, stochasticity is ubiquitous even in consistent and patterned behavior. Even when specific sequences of behavior are selectively rewarded, the manifestation of other behavioral combinations persists at background levels (Stokes 1995). The degree of uncertainty in any measured behavior can be described, in absolute or relative terms, using the tools of information theory (Jensen et al. 2013).

Even very simple mechanical systems, such as two-armed pendulums, can display highly unpredictable behavior, a phenomenon studied by chaos theory (Robertson and Combs 1995). Braitenberg (1986) demonstrated the relevance of this to the behavior of organisms with his “vehicles” (so-called because they were too simple to be called “robots”). Despite having only rudimentary sensors and motors, connected in a non-networked fashion, these deterministic virtual agents displayed highly variable and intentional-seeming behaviors. A big reason for this emergent variability is that even with a simple mechanical agent, any realistic environment is full of variation (e.g., uneven terrain or luminosity). If behavior varies in response to the interaction between the agent’s moving frame of sensory reference and the natural variations in environment, that variability may be described as having been “induced” by the environment. If, on the other hand, the source of variation is internal to the agent (such as fluctuations in the electrochemical signaling of long-range neurons), then it may be described as “intrinsic.”

Both induced and intrinsic stochasticity in behavior are usually seen as passive, in the sense that they are treated as residual error from some measured central tendency. Nevertheless, they are

useful measures, particularly when taken longitudinally. Given that induced variability requires sensitivity to environmental cues, compromised health in many cases results in reduced behavioral variability. Similarly, insofar as intrinsic variability arises from the complex interactions of different body systems, dysregulation can result in more stereotyped patterns of activity. For example, reduction of heart rate variability (HRV) is a common symptom of myocardial difficulty (Malik and Camm 1994). When asked to generate motor movements, patients with a schizophrenia diagnosis generally produce more stereotyped motions (Hornero et al. 2006). Measuring changes in “intraindividual variability” over time can also be a revealing diagnostic indicator in age-related cognitive decline and dementia (Martin and Hofer 2004). Although there is a popular conception that pathology, and especially mental illness, results in behavior that is “more random,” it is instead typically the case that behaviors that are symptomatic of pathology are socially inappropriate (and thus unexpected), rather than being unpredictable *per se*.

A commonly reported form of induced behavioral variability is that observed during the extinction phase of a schedule of reinforcement. In general, once subjects become accustomed to a reliable contingent relationship between rewards and behavior, cessation of rewards results in a dramatic increase in the variability of behavior (Stokes 1995). According to a very long tradition in animal psychology (reviewed in Guthrie and Horton 1946), the great diversity of these “frustration” responses creates a strategic opportunity, because animals may discover that a never-before-tried behavior is able to resolve their current difficulty. This result, in particular, blurs the line between variability that is incidentally induced and that which serves a functional purpose.

### Strategic Stochasticity

Although all behavior necessarily has a random component, it is sometimes adaptive to behave very unpredictably. One example of this is

“protean behavior,” in which animals react to an alarming stimulus (such as a loud noise or the appearance of a predator) by moving in a fashion that is difficult for an observer to predict (Driver and Humphries 1988). As in all cases of strategic stochasticity, the scope of this variability is constrained. For example, a hare who is evading a fox will intermix leaps forward, to the left, and to the right in a way that is difficult for a less maneuverable fox to anticipate. However, such protean escape behavior never includes random freezing or backward motion: The hare will always move away from the fox.

Being difficult to capture confers a clear evolutionary advantage to prey animals, but the same selective pressures operate on predators. The gains in fitness from protean behaviors can thus best be understood in terms of what game theorists called a “mixed strategy” (Barracough et al. 2004). Since any prey animal using a simple strategy (such as “run straight”) would ultimately have a predator adapted to defeat that strategy, being entirely random (including stopping) is almost always counterproductive, as a species is expected to adapt a level and scope of behavioral stochasticity that balances the benefits of predator confusion with the costs of accidentally counterproductive behavior (such as leaping into a predator’s jaws).

Stochasticity is not only strategic at evolutionary scales. It is also beneficial for most animals to learn when to behave more or less randomly in response to environmental cues. In foraging problems, for example, the complexity of the environment usually exceeds the memory capacity and/or spatial reasoning ability of the animals that inhabit it. A limited and contextually sensitive degree of variability is important to discovering opportunities that might otherwise have gone undetected (Stephens and Charnov 1982). There are perhaps no organisms more limited in memory capacity than *E. coli* bacteria. When moving through a medium interspersed with nutrients, these bacteria move in straight lines as the nutrient gradient increases but are more likely to tumble randomly as the gradient decreases (described in Driver and Humphries 1988). This cognitively minimal approach (vary when bad, maintain when good)

effectively replicates a Monte Carlo algorithm for mapping the relative density of nutrients (Siettos 2014).

As noted in the preceding section, behavioral or autonomic stereotypy can be an indicator of poor health or neural dysregulation. This may explain why, in some contexts, behavioral variability is an honest signal of fitness and thus the object of sexual selection. The clearest example of this is bird song: In a variety of species, female songbirds display a preference for males who display more complex songs, as well as to modulate their level of variability on the basis of cues, such as whether a female is currently visible (Catchpole and Slater 1995). This implies that birds are able to perceive differences in levels of variability (Young and Wasserman 2001). When vocalizing for rewards, the variability of bird song has even been shown to come under stimulus control (Manabe et al. 1997).

This last study is just one example of a body of work showing that many species display considerable behavioral stochasticity when incentivized to do so. According to this view, the stochasticity of a behavior is an “operant,” that is, a dimension of behavior that can be manipulated through the delivery of feedback (reviewed in Neuringer (2002) and Neuringer and Jensen (2010)).

A major advance of this field was made by Page and Neuringer (1985). Pigeons were initially rewarded for emitting novel sequences of left and right key presses (labeled the “VAR” phase). During this time, the sequence of which trial numbers were rewarded or not was being recorded. Then, in later sessions (the “YOKE” phase), the previously recorded sequence of rewards was delivered again, trial by trial, regardless of the patterns that subjects generated. By directly measuring the information entropy of sequences of behavior during both phases, Page and Neuringer showed that subjects generated high-entropy sequences during VAR and low-entropy sequences during YOKE, despite the two phases having identical reward histories. Under the traditional Skinnerian interpretation of an “operant,” contingent reward delivery should result in increasing behavioral stereotypy. By showing that variability itself acts as an operant, the authors demonstrated that

rewards could decrease stereotypy, provided that positive feedback was contingent on highly variable behavior. Subsequent work by Neuringer and colleagues demonstrated similar reward-contingent variability in rats (Grunow and Neuringer 2002) and humans (Jensen et al. 2012).

As in the evolutionary example of predator avoidance above, studies of operant variability also demonstrate that variability only increases within the scope of what is functionally advantageous. In an especially striking study, Ross and Neuringer (2002) had human participants draw rectangles using a computer mouse. Each response could vary independently in terms of (1) the position of the rectangle’s center, (2) its total area, and (3) the ratio of its length to its width. Participants earned rewards by varying two of these dimensions while keeping the third static but were never given instructions regarding the experiment’s objective. Furthermore, over the course of the experiment, there were unsignaled changes in which of the three dimensions needed to be held constant. Participants reliably varied their responses only among the two target dimensions, adapting to the changing feedback. However, when debriefed, participants were generally unable to describe the strategy they had used, despite succeeding at the task.

## Stochasticity’s Underlying Mechanisms

The mechanical origin of stochastic behavior remains a topic of debate among theorists. According to one view, the studies above do not really demonstrate that behavioral stochasticity is sensitive to feedback as such. Instead, changes in variability are seen as the product of traditional reinforcement learning mechanisms (Machado 1997). In effect, behavioral variability is the result of feedback constantly moving the behavioral target that an organism is trying to approximate. As with Braitenberg’s “vehicles,” the source of behavior’s apparent variability is, according to this view, the organism’s interaction with a changing and unpredictable environment. Others have gone further to argue that variability cannot sensibly be described as a dimension of behavior on

which feedback can operate (e.g., de Souza Barba 2012). This view is not skeptical of the phenomenon of apparently stochastic behavior; rather, it argues that the origins of that stochasticity can be explained in mechanistic (or even deterministic) terms, using mechanisms like reinforcement learning and implicit memory.

At the opposite extreme, Neuringer (2002) argues that behavior has an intrinsically stochastic substrate that is sometimes suppressed and at other times given control. For a given behavior, an “endogenous stochastic generator” (ESG) would generate variability by default, and the ESG would need to be inhibited in order for behavior to appear stable or structured. The core of Neuringer’s argument is that a memory-based model may explain a task in which subjects generate simple sequences but that more complex sequencing (or behavior varying along a spatial continuum) yields a combinatorial explosion of possibilities that cannot be manageably encoded. Furthermore, pharmacological manipulations that impair memory, such as D-amphetamine (Ward et al. 2006), undermine memory-based performance but do not undermine feedback-driven stochasticity. Tervo and colleagues (2014) report a possible neural mechanism consistent with an ESG hypothesis: Transitions between structured and stochastic behavior appear to be governed by the locus coeruleus input into the anterior cingulate cortex (ACC). According to this interpretation, stochastic behavior is observed when the ACC is suppressed, as this results in behavior that is less dependent on memory or past experience.

As the study of variable or unpredictable behavior has transitioned to a more cognitive mode of theorizing, the basic debate remains: When variable behavior is observed, is it the result of a model the brain has constructed of the world, or is it due to the brain setting aside its model in favor of a more exploratory strategy? Given the ubiquity of reward/punishment signals in the brain and the consensus view that these signals are used to educate internal models of the world using error prediction (e.g., Nassar et al. 2010), it would be disadvantageous for learned models to become hard-wired, as this would leave

organisms of a certain age unable to adapt to changing circumstances. When the mind’s present model fails, the brain needs a way to “opt out” of its own model (Karlsson et al. 2012). Defaulting to high-variability behavior provides a way to do so.

The widespread consensus in behavioral neuroscience is that organisms rely on induced intrinsic variability as a source of behavioral variation (Gold and Shadlen 2007). This not only has the advantage of making mixed strategies cost-effective (since unpredictability can always be called upon) but also for engaging in exploratory behavior in novel environments without needing a prior history of feedback. This view is more compatible with Neuringer’s ESG hypothesis than it is with de Souza Barba’s skepticism. However, rather than freeing behavior from a Skinnerian model shaped by reinforcement, the approaches utilized in neuroscience emphasize the brain’s simultaneous reliance on cognitive models and (when past models are not effective) their occasional reliance on intrinsic variability to escape the behavioral constraints imposed by those models.

## Synonyms

[Behavioral diversification](#)

## Definition

Variations in the behavior among individuals belonging to the same species in response to genetic, phenotypic, or environmental changes.

## Introduction

Study of behavioral variation concerns with the behaviors displayed by individuals and how these behaviors vary among individuals both within and among populations. Animals have evolved specific contextual behaviors, such as defense, reproduction, and exploration. Variations in these behaviors have fundamental implications on an individual's ability to acquire, process, and respond to novel information or stimuli. These differences in behaviors can result from differences in life history stage, i.e., juveniles vs adults, or physiological differences, i.e., healthy vs diseased individual. The study of behavioral variations helps in understanding the impact of altered environmental factors and population shifts in genetic/phenotypic differences.

## General Description

Consistent individual differences in behavior, frequently termed as behavioral syndromes or animal personality are set based on the degree of behaviors like aggression, foraging activity, vigilance, competitive interactions, predator-prey interactions, habitat selection, risk-taking, and singing displayed by the animal. These individual variations occur due to genetic or phenotypic variation and differences in life history stages. The personality of the animal acts as a deciding factor during courtship, mate choice, escape from predators, or survival against harsh climatic conditions (Killen et al. 2013). These variations are also reflective of an individual's response to various stressors, owing to the differential sensitivity of animals in response to the changing environment. Certain behaviors may be masked or revealed based on how the individual responds to stress. Like for example, dark-eyed junco groups

become less aggressive during the winter. Ecological changes, behavioral, and physiological responses are interlinked and have a cause-and-effect relationship wherein slight shift in the former will cause variations in the latter two. For example, fasted animals generally show increased boldness during foraging activity. Environmental stress, such as food deprivation, causes physiological changes which can result in consistent behavioral differences among individuals or in a group, eventually leading to phenotypic variation. As a result, behavioral variation precedes morphological modifications followed by ecological speciation (Phillips and Suarez 2012).

These behavioral variations also cause changes at the neuronal level. One form of behavioral variation is observed in seasonally breeding birds and migratory birds. Migratory birds display a behavior known as *Zugunruhe*, also known as night-time restlessness, which is a migratory preparedness behavior displayed when there is a shift in photoperiod from short day to long day and vice versa. The birds during this stage undergo physiological changes in the form of increased fat accumulation, hyperphagia in preparation for migration, change in testicular volume, and changes in neuropeptide levels in the migratory brain regions (Mishra et al. 2016). Similarly, in seasonally breeding bird species, the males display directed singing and nest building behaviors while courting the female and the volume of song control areas in the brain increases during this stage (Healy et al. 2010). Sudden changes in behavior cause the brain areas responsible to express immediate early genes (IEG) like *c-fos*, *ZENK*, etc (Sadananda and Bischof 2002). Increased expression of these molecules in conjunction with increased levels of corticosteroid is taken into consideration while studying behavioral response of an animal to the novel object.

## Conclusion

These adaptive changes not only influence the survival of the individual/species but also play a role in ecological speciation. Any variation in behavior can be traced back to changes in

neuropeptide, immediate early genes (IEG), and neurotransmitter levels in related brain areas.

- as to how the mind organizes information, the factors that affect the mind, and the structure of the mind. Sigmund Freud contributed to this mentalistic approach by focusing on internal conflicts that take place in the unconscious mind and how these unresolved conflicts could lead to psychopathology. Freud's work spread quickly and took a stronghold in Europe. Many psychologists in the United States believed in Freud's work, but there were a few who wanted psychology to return to a science, including John Watson.
- John Watson founded behaviorism with the goal to scientifically study human behavior (Watson 1913). The primary goals of behaviorism are to predict and control behavior, with the secondary goals focusing on a scientific and objective approach to measuring and explaining behavior. This movement led to the scientific advancement of psychology as theories, methodologies, and its applications began to rely on objectivity.
- As psychology was advancing, so was behaviorism. There are three stages of behaviorism: associationism (1897–1930), neobehaviorism (1930–1960), and sociobehaviorism (1960–Present). Together, these three schools of thought informed research and its application in psychology.

## Associationism

The associationism period formally began in 1870, but learning by association was discussed more than 2000 years ago by Aristotle (Schultz and Schultz 2016). Aristotle suggested that humans learn by associating an object and a response together. Aristotle's work was revisited by the British associationists, British philosophers, especially by John Locke and David Hume. They spoke about how associations could lead to reflexive responses, particularly as the strength of the association increased (Schultz and Schultz 2016). Locke referred to humans' minds as *tabula rasa*, meaning blank slate. He believed human beings are born without knowledge and that all learning occurs as a result of their experiences. Hume argued that all thoughts are a result of the individual's experience, specifically the individual's impression of a stimulus determines their

## Introduction

Psychology initially lacked objectivity, and thus it was difficult to label it as a science. Drawing on Wilhelm Wundt and Edward Titchener's works, psychology was focused on examining one's consciousness through introspection. Psychologists at the time were not concerned with observable behavior but rather mental states such as thoughts and feelings. From this, assumptions were made

ideas. This is to say, the individual does not have unique thoughts, but rather his thoughts are dictated by linking impressions and ideas learned in his experience. These links are solidified through resemblance, contiguity, and cause and effect (Hume 1740/2012). While Hume's ideas about solidifying the relationship between impression and ideas were found to be true, there was no scientific evidence for this at the time.

Ivan Pavlov's (1849–1936) work on *classical conditioning* was the first scientific support for associations. Pavlov, a Russian physiologist, noticed that immediately before he went to feed his dogs, they were already salivating; it was almost as if they knew they were going to be fed. Being an effective scientist, Pavlov systematically examined this behavior. Pavlov's typical experiment involved a dog in a dark room. A light would turn on, and 30 s later, food was presented,

eliciting the salivation response (Pavlov 1928). This pairing occurred several times and resulted in the dog salivating once the light was presented, even if the food was not presented. Pavlov showed that the dog was conditioned to salivate when the light was turned on.

In classical conditioning terms (Pavlov 1928), the food is known as an unconditioned stimulus (US). The unconditioned response (UR) is when the dog automatically salivates as the food is presented. The light begins as a neutral stimulus (NS) and as it is repeatedly paired with the US, the light becomes known as the conditioned stimulus (CS). The repeated pairing of the US and CS conditions a dog to salivate when the room is lit, the conditioned response (CR; see Fig. 1).

Another common example of classical conditioning (aka respondent conditioning) that Pavlov studied was teaching a dog to salivate to the sound

Behaviorism, Fig. 1 Classical conditioning

of a metronome. The sound of a metronome begins as a NS, as it does not originally produce a response. Presenting food, the US, elicits a salivation response/reflex, a UR, from the dog. If the experimenter were to present the metronome and then shortly afterward present the food, the dog would salivate. After several trials, the sound of the metronome, the CS, becomes paired with food, and the dog elicits a salivation response, CR, even when just the metronome is presented. Take note that in both examples, the CS was presented *shortly before* the US. Studies have shown that conditioning a response when the CS is presented after the US is not very effective (Pavlov 1927). In fact, conditioning occurs most rapidly when the CS is presented one-half second before the US.

Throughout his work, Pavlov founded several principles of conditioning, such as extinction, stimulus generalization, stimulus discrimination, and higher-order conditioning.

### Extinction

A CS can cease to produce a CR if the CS is repeatedly presented alone. By repeatedly presenting the light without the food, the dog learns to not salivate. This process is known as *extinction* (Pavlov 1927, 1928). Pavlov found that even when the CR seems to be extinguished, it is possible for the CR to reappear after the CS has not been presented for some time. Pavlov labeled this *spontaneous recovery* (Pavlov 1927, 1928). Let's use the example above. A dog is trained to salivate when light is paired with food, but after several trials of presenting the CS alone, the dog no longer salivates. If a delay of several hours is administered before the next presentation of the CS, the dog is likely to produce the CR, even though the CS and the US were not paired together. Spontaneous recovery can be extinguished by repeatedly presenting the CS without the US. If the CS and US were occasionally paired together during this process, it would only strengthen the association.

### Stimulus Generalization and Discrimination

In most classical conditioning experiments, only two stimuli are paired together, the CS and the US; however, the CR will be elicited not just from the

CS but also from similar stimuli to the CS. The more similar a stimulus is to the CS, the more likely it will elicit the CR. This process is known as *stimulus generalization* (Pavlov 1928). Let's refer back to Pavlov's prototypical study where he paired a metronome (CS) with food (US), causing the dog to salivate. After several pairings, the dog is likely to salivate to the stimuli resembling the sound of the metronome, such as wind chimes, a doorbell, or hitting a glass with a utensil. The dog is not likely to salivate to sounds that do not sound like a metronome, such as dropping a book on the floor, making a cup of coffee, or a siren wailing. This ability to differentiate between the CS and other stimuli, and not produce the CR, is known as *stimulus discrimination* (Pavlov 1928). Pavlov could enhance the dog's ability to discriminate between the CS and other stimuli by deliberately pairing the metronome with food and then present another tone without the food. The dog will begin to discriminate between the two tones and respond just to the CS.

### Higher-Order Conditioning

Pavlov took his research one step further by demonstrating that once a dog was fully conditioned to a CS, he could then pair the CS with a new NS. The previous CS takes the place of the US and is known as a first-order CS. This process is called *higher-order conditioning* (Pavlov 1928). For example in second-order conditioning, Pavlov trained a dog to salivate to a metronome (the first-order CS) and then paired it with a black square (the new CS), to teach the dog to salivate at the sight of a black square. Pavlov found in some instances third-order conditioning could be derived; however, he could never surpass third-order conditioning.

### John Watson

Pavlov's work on classical conditioning became more influential when John Watson made it the bedrock of his theory, behaviorism. Watson was not happy with the direction of psychology, as he viewed it to be unsystematic. In 1913, Watson published the article "Psychology as the Behaviorist Views It," commonly known as the "Behaviorist Manifesto." Watson proposed that a

behaviorist views psychology as a purely objective science, concerned with only what is observable and objectifiable. This was contrary to mainstream psychology of Watson's time. Most psychologists believed in introspection and consciousness. Watson rejected these terms because they were not observable and could not be empirically validated. He treated psychology as a science and promoted operationalism through clearly defining terms and observing behaviors. This branch of behaviorism is known as *methodological behaviorism*.

Watson envisioned behaviorism as the *prediction* and *control* of behavior based on sound scientific methods. Watson and Rayner (1920) demonstrated this through classical conditioning. In his famous experiment, Watson took a 1-year-old boy named Little Albert and conditioned him to be afraid of a white rat. Watson first measured Albert's baseline by observing Albert's physical response when he was presented with a white rat, rabbit, dog, monkey, seal fur coat, Santa Claus mask, and fire. Albert had a positive response to these stimuli, according to Watson's report. Watson then presented a white rat to Albert while simultaneously hitting a steel bar with a hammer. The loud noise was an aversive stimulus to Albert. Watson repeated the pairing several times and Albert began to cry. Watson then presented the rat alone and it evoked a fear response, known as a *conditioned emotional response*. Albert's fear response of crying and crawling away from the stimulus generalized to animals and objects like a white rat (e.g., rabbit, fur coat, Santa Claus mask). An example of stimulus discrimination, Albert did not emit a fear response when presented with a monkey, as the monkey did not resemble the white rat (Watson and Rayner 1920).

Watson never cured Albert's conditioned fear response, as Albert's mother and him moved at the end of the experiment. In 1924, Mary Cover Jones worked on her dissertation under the supervision of John Watson and provided methodological behaviorism with the first glimpse of applied research and a treatment approach. She tested a variety of methods to eliminate the fears (e.g., frogs, fish, rabbits, rats) of a 3-year-old boy named Peter, most notably systematic desensitization and

modeling (discussed in detail later in the chapter). Cover Jones drew on Pavlov's and Watson's works on how conditioned emotional responses form. She recognized that Peter learned to associate rabbits as an aversive stimulus and, therefore, avoided rabbits. Cover Jones decided to recondition Peter by incrementally exposing him to a rabbit with an appetitive stimulus present. Cover Jones placed Peter in a high chair with his snack (an appetitive stimulus) and positioned a caged rabbit across the room. Initially, Peter expressed fear, but after several presentations, the fear response subsided. The following day, Cover Jones brought the caged rabbit within 12 ft. of Peter as he was snacking, which was just enough to evoke a slight arousal from Peter. She repeated this process for several days, each time bringing the rabbit closer and closer to Peter. She eventually let the rabbit out of its cage and had Peter touch the rabbit. The last two steps in this hierarchy were to have Peter fondle the rabbit affectionately and then to let the rabbit nibble his fingers (Cover Jones 1924). This study is the beginning of *systematic desensitization*, which is still commonly used to treat anxiety.

### Behavior Therapy

Cover Jones's work on systematic desensitization earned her the title "Mother of Behavior Therapy." Her work went largely unnoticed until Joseph Wolpe, a psychiatrist from South Africa, formalized the treatment approach (Wolpe 1958). In 1944, Wolpe was working as a military medical officer and found psychoanalysis to be ineffective in treating "war neurosis"; as such, when he returned from the war, he began to research an effective way to treat neuroses. Using cats as his subjects, he placed them in a cage and shocked them repeatedly until it produced an anxious response. Trying to cure this response, Wolpe attempted several unsuccessful methods, including no longer shocking the cats when they were in the cage. What he did find to be effective was to leave the cats in a *slightly* anxiety-producing situation (e.g., shocking them) to the point where they would still eat. Wolpe would repeat these exercises, gradually increasing the intensity. The cats eating while anxious is an example of *reciprocal inhibition* or counterconditioning

(Wolpe 1958). Reciprocal inhibition is the process where an organism cannot be relaxed and tensed simultaneously, and, therefore, the feeling of anxiety can be *counterconditioned* if the organism performs a relaxing behavior (e.g., eating). In Wolpe's study, the cats eating inhibited the cats' anxiety.

Wolpe created four steps for systematic desensitization in humans: diagnose the patient, construct a hierarchy, teach relaxation, and conduct therapy sessions (Wolpe 1958). The first step was to examine the presenting problem and provide a correct diagnosis. Then, the therapist and patient created a hierarchy of anxiety-producing situations ranging from least anxiety producing (0) to most anxiety producing (100). Wolpe found that instead of instructing his patient to eat when feeling anxious, teaching him (her) how to relax via progressive muscle relaxation (PMR; Jacobson 1938) inhibited their anxiety. PMR involves the patient tensing different muscle groups in their body and then relaxing via deep breathing. Lastly, Wolpe would expose the patient to low-grade anxiety-producing situations, and the patient would practice PMR until their anxiety had reduced to 20 or lower. He would continue this process, gradually climbing up the hierarchy. Wolpe found systematic desensitization to work especially well when treating phobias, an extreme or irrational fear.

Wolpe believed that the principle of reciprocal inhibition could be applied to those who feel socially anxious, as well as those who feel angry. He was a pioneer of a technique called *assertiveness training* (Wolpe 1958). Similar to when he was treating those suffering from anxiety, assertiveness training involves counterconditioning the patient's angry or passive response with a friendly and affectionate response. Wolpe would have his patients practice the assertive response in the therapy session to replace the patient's passive or aggressive response.

Wolpe's work on systematic desensitization, assertiveness training, and applying PMR earned him the title "Father of Behavior Therapy." His work led to many other great findings, including exposure therapy (Telch et al. 2014). Exposure therapy is similar to systematic desensitization,

in that the patient is exposed to fearful stimuli; however, the fundamental premise is different. Systematic desensitization is based on the principle of reciprocal inhibition (Wolpe 1958), whereas exposure therapy is based on habituation (cf. Schare and Itzkowitz 2017). Systematic desensitization attempts to gradually replace an anxious behavior with a relaxing behavior. Exposure therapy immerses the patient in a highly anxiety-producing situation, and the anxiety-provoking stimulus is repeatedly presented until the patient's arousal level begins to decrease. A key component of exposure therapy is preventing escape (leaving an anxiety-producing situation) and avoidance (not engaging in anxiety-producing situations). Escape and avoidance both work against habituation and only increase the association between the stimulus and anxiety and the patient's response. Exposure therapy is just as effective as systematic desensitization and requires considerably less time in treatment. Habituation is likely to occur at a faster rate if the stimulus is high intensity and presented frequently. Exposure therapy is used to treat anxiety disorders, obsessive-compulsive disorder (OCD), and posttraumatic stress disorder (PTSD).

Exposure therapy can be conducted one of three ways: imaginal, in vivo, or virtual reality (VR). Imaginal exposure therapy involves having the patient visualize the anxiety-provoking stimulus. The benefits of imaginal exposure are that it does not require any additional resources on the part of the therapist and the therapist controls the stimulus. In vivo exposure involves presenting the patient with the real anxiety-provoking stimulus (e.g., spider, heights, social rejection). The drawback of in vivo exposure is the therapist's lack of control over the environment. The therapist has more control over creating an imaginal stimulus as opposed to presenting an in vivo stimulus. VR exposure is relatively new and provides an alternative to imaginal and in vivo exposure (Parsons and Rizzo 2008). In VR exposure, the patient is presented with a virtual creation of the target stimuli. The therapist has control over what stimuli are presented (contrary to in vivo exposure), and it is one dimension closer to resembling a real stimulus compared to imaginal exposure. Current

research is inconclusive as to which approach is most effective, though all three approaches are validated (cf. Telch et al. 2014; Parsons and Rizzo 2008).

Pavlov's work on classical conditioning has been very influential in explaining how learning occurs through associations and has led to the abovementioned therapeutic techniques. It has helped not only explain, control, and predict behavior but also replace maladaptive behaviors with more functional behaviors. However, it cannot explain how all behaviors are learned, and as such, researchers continued to look for other explanations.

## Neobehaviorism

### Methodological Behaviorism and Radical Behaviorism

While scientific method legitimized psychological research and gave merit to the field, observable behavior alone cannot account for the entirety of an organism's experience. *Radical behaviorism* posits that there is merit to considering the private mental activity of an organism (such as thoughts and feelings), along with biological factors and genetic factors. Yet, radical behaviorists do not believe that private experiences are a cause of behavior. Radical behaviorists seek to demonstrate connections between behavior and environment and are focused less on causation due to thoughts and feelings (Baum 2011).

Early insights that contributed to the philosophy of radical behaviorism were provided by early psychologist *Edward Lee Thorndike* in the late nineteenth century. Thorndike aimed to investigate animal intelligence. He confined a cat inside a puzzle box that contained various objects, some of which would open the box and encouraged the cat to escape confinement by placing a scrap of fish outside the box. Thorndike took care to record the specifics of his experiments, from the dimensions of the boxes to the ages of the thirteen cats he used as subjects (Thorndike 1927). This showed an experimental design that diverted from the common case study approach that was popularized in psychology at the time and several years before

Watson introduced the Behaviorist Manifesto. Thorndike's experiment could be replicated by any interested reader and featured multiple subjects (a group of cats instead of one individual cat). These studies reflected the scientific integrity and objectivity that Watson later promoted as a tenet of behaviorism.

Each cat was placed in the same puzzle box several times over. Thorndike observed that the first time the cats escaped, it was by trial and error. The cats would claw or bite objects until the door opened. Every time the cat was placed back in the box, they would escape faster than the previous time. The cats learned that manipulating certain objects led to a favorable outcome that freed them. Thus, Thorndike deduced that the cats learned how to open the box through successive trials. Thorndike termed his resulting theory the "law of effect," which stated that when a behavior has a satisfying consequence, the behavior would be more likely to be repeated and when the response is unpleasant, the behavior would be less likely to be repeated. Thorndike viewed the cats as being "pleased" by escaping the box and attaining the fish, which caused them to escape the box quicker (Thorndike 1927). From Thorndike's foundations and theory of behavior came a new model of operational behavior or behavior that operates on the environment the way that the cats manipulated objects to leave the boxes.

### Skinner's Operant Conditioning

The model of operant conditioning that Thorndike conceptualized was later actualized by B.F. Skinner. Skinner was an inventive, studious man who attended college intending to study writing. Yet, he left graduate school in the pursuit of psychology because he had "nothing important to say" as a writer (Skinner 1967). His research built upon the findings of Thorndike and Pavlov, and yet, Skinner moved away from their ideologies in his own conceptualization of behavior. Skinner believed that Thorndike's references to mental states using the term "pleasure" was an inaccurate label to use when it came to studying behavior. In addition, Skinner (1938) did not completely believe that Pavlov's (1927) work on reflexive behavior accounted for all learning. For example,

a student may tremble at the sight of their teacher carrying a large stack of exam papers into the classroom. Yet, classical conditioning cannot account for why the same student studied every day for an entire week leading up to the exam. Skinner's resulting conclusion was that there must be another way to learn behavior, because not every behavior is reflexive. He referred to these other behaviors as being "emitted" by an organism and explained these emitted behaviors through operant conditioning.

*Operant conditioning*, or instrumental learning, was defined by Skinner as behavior that occurs because it was previously instrumental in producing certain consequences (Skinner 1938). It is a behavior that changes consequences in an organism's environment. For example, it is a logical assumption that the student studied every day for their exam so that he would receive an impressive grade on the exam. This student may have learned that when he operates in a certain way and carry out a certain behavior (in this case, studying), his grades improve. A grade is an outcome that makes the student study more, and by studying, the student "operates" upon their environment. Or, perhaps this same student did not study for a previous test in this same class and they received a poor grade. The student's studying behavior could also be a way to avoid an unfavorable grade. The student's studying behavior is instrumental in establishing the outcome. This led to Skinner's development of the "Law of Effect – Reinforcement," where he identified that behavior that is reinforced will repeat and is "strengthened" and that behavior that is not reinforced will extinguish or "weaken" (Skinner 1938).

To study the ways that organisms operate upon their environments, Skinner created boxes similar to Thorndike's, referred to as "Skinner boxes." An animal, such as a rat, would be free to move around the box. A lever in the box, when pressed, would deposit water or a food pellet. The rat would press the bar and receive the reward and having been reinforced for pressing the lever would be more likely to press the bar with greater frequency. The *rate* of the response increased due to the rat being positively reinforced. The *operant response*, in this case the lever press, has a

positive effect on the environment and will be more likely to be repeated (Skinner 1938).

## Contexts of Operant Conditioning

### Reinforcement

Skinner (1938) identified that there were three types of responses that could follow behavior: neutral, positive, and negative. A neutral operant is a response from the environment that does not increase or decrease the amount of times that a behavior is repeated. Reinforcement is a response that increases a behavior and can be either positive or negative. It is important to note that the terms "positive" and "negative" are used to refer to "addition" and "subtraction," respectively. They are not supposed to signify something that is "good" or "bad."

*Positive reinforcement* is when a behavior is strengthened through the addition of a rewarding stimulus (Skinner 1938). Imagine that when a child makes his bed, he receives \$10 from their parents. He is positively reinforced (\$10) for his behavior (making the bed), which will make him more likely to make his bed in the future. Or let's consider the student who studied for his test because they received a good grade when he studied in the past. The good grade is the reinforcer, and the behavior is studying. Skinner praised positive reinforcement as the most effective way to reinforce a behavior.

*Negative reinforcement* is when a behavior is strengthened through the removal of an aversive or noxious stimulus. A negatively reinforced behavior allows the animal to escape from an unpleasant stimulus/consequence (Skinner 1953). There are two specific types of negative reinforcement: escape and avoidance. *Escape* is when an animal attempts to alleviate an aversive stimulus by leaving an unpleasant condition. An example of this is when someone takes an aspirin to alleviate a headache. Taking aspirin removes the aversive headache, so the behavior is negatively reinforced. On the other hand, *avoidance* is when an animal engages in a behavior to prevent the presence of an aversive stimulus. Putting on sunscreen before a day at the beach is a behavior to avoid a future negative consequence (sunburn).

Reinforcers can also be “primary” or “secondary.” A *primary reinforcer* is a reinforcer that is satisfying on its own without being linked to another reinforcer. This can include food, water, sleep, shelter, touch, or feelings of pleasure. All of these examples have innate reinforcing qualities to organisms. A *secondary reinforcer* (also referred to as a conditioned reinforcer) has no innate reinforcing value until it is linked with a primary reinforcer – one example is money. Green pieces of paper are not innately reinforcing to humans. Yet, humans learn that money can be used to acquire primary reinforcers (e.g., food, water, shelter). This paired association is what makes money reinforcing.

### Punishment

Reinforcement is a stimulus that increases the likelihood of a behavior, while punishment is a stimulus that decreases the likelihood of a behavior. The term “punishment” does not have any connotation of “good” or “bad” in behaviorism. Instead, it simply indicates a decrease in a response. There can also be positive and negative types of punishment, like positive and negative reinforcement.

*Positive punishment* is when an unpleasant stimulus is introduced to decrease or weaken a behavior (Skinner 1953). A classic example of positive punishment is corporal punishment. Perhaps a parent hits a child after the child steals from the cookie jar before dinner. The unpleasant consequence (hitting) will decrease the undesired behavior in the future (stealing cookies). However, in behaviorism, the term “punishment” does not always indicate a penalty. Another example of a punisher is when the child leaned on the counter to get into the cookie jar, and rested their hand on the hot stove in the process. The introduction of an unpleasant consequence (a burned hand) will decrease the likelihood that the child will engage in the behavior (touching the stove to get the cookie jar) in the future. Thus, the cookie-stealing behavior is weakened.

*Negative punishment* is when a favorable stimulus is removed after a behavior occurs, to decrease or weaken the behavior (Skinner 1953). One common example of negative punishment is

when a student breaks the rules and receives detention. The student is removed from a favorable environment (leaving school on time to go home) in order to decrease their rule-breaking behavior. Another example of this is placing children in time-outs or when a parent takes away cellphone/computer/TV usage. There is no noxious consequence added, but there is something positive taken away, and this removal of the positive consequence will cause a reduction of the undesired behavior (see Fig. 2).

**The Case against Punishment** Skinner spoke out against all uses of punishment and stated that they were ineffective compared to reinforcement. He expressed that while punishment is the most common type of behavioral control used in the world, that punishment would only temporarily “suppress” a behavior and that it could create other unwanted consequences (e.g., fear and aggression; Skinner 1953). There is some sound logic in Skinner’s claims. When an animal is punished, a response is decreased, but, if a desired target behavior is never increased, the animal will not have any other response to the stimulus. Punishment *does not* promote learning. It is commonly accepted that when an undesired behavior is decreased, a desirable target behavior should be increased as well. If a teacher ignores a child every time the child speaks without raising her hand, the teacher should call on the child when she raises her hand appropriately (and can even compliment the child, as well).

Instead of punishment, Skinner believed in extinguishing behaviors through nonreinforcement and spoke out widely against the use of punishment to control behavior. Research was conducted in a laboratory on the same floor as Skinner’s office by Tom Azrin who attempted to undermine Skinner’s poor view of punishment. Overall, Azrin and his colleague Holz (Azrin and Holz 1966) determined that punishment is uniquely effective compared to other forms of behavioral suppression. When performed correctly, punishment is just as effective in extinguishing behavior as extinction. Punishment operates on a different schedule of effectiveness compared to reinforcement. Continuous punishment produces the

**Behaviorism,**  
**Fig. 2** Operant  
conditioning

greatest reduction of behavior, rather than an intermittent schedule of punishment. A sudden introduction of an immediate and intense novel punishment is the most effective way to use punishment to reduce behavior.

There are times that punishment has an appropriate place in behavioral reduction. Lang and Melamed (1969) treated a 9-month-old infant who was regularly regurgitating his food. The infant was at risk of death due to starvation. The only solution that worked after multiple failed medical interventions was to provide a brief, painful shock to the infant's leg every time he began to regurgitate. This is an example of an ethical use of positive punishment. This life-saving punishment procedure reduced the undesirable behavior faster than extinction would have.

#### Schedules of Reinforcement

Behavior is rarely *continuously* reinforced; more often, animals are reinforced *intermittently*, meaning that reinforcement is not always consistently contingent upon the introduction of a stimulus. For example, a cat that prowls the streets for a good meal might not catch a mouse every time he goes out hunting. Yet, the cat does not stop hunting, as the cat has been reinforced for

it. It is important to understand the *schedule of reinforcement* or the schedule that determines how often a reinforcer is delivered after a behavior. These schedules affect the ways that an animal learns a response and then how the response is maintained over time (Ferster and Skinner 1957).

Continuous reinforcement is most effective when first beginning to teach a response. To teach a dog to sit on command, the most effective method is to reward the dog for sitting every time she hears the word "sit." Two paradigms define intermittent schedules of reinforcement: *fixed* or *variable* and *interval* or *ratio*. Fixed reinforcement refers to a set number of responses or length of time between reinforcements. Variable refers to when the number of responses or length of time varies. Intermittent reinforcement can also be delivered on an *interval* or *ratio* basis. Interval means that the schedule is based on the amount of *time* that passes between the reinforcements. Ratio means that the schedule is based on the *number of responses* between reinforcements. Thus, there are four different types of intermittent reinforcements. These are listed in order from the "weakest" to "strongest" (Ferster and Skinner 1957).

A *fixed-interval schedule* of reinforcement is when a behavior is rewarded after a set amount of

time. A washing machine that always runs on a 45-min cycle operates on a fixed interval of reinforcement. The individual doing laundry will be more likely to perform the reinforcing response (checking to see if the clothes are clean) closer to the end of the 45-min time frame, opposed to immediately after the laundry is loaded. There is a significant pause after reinforcement, where the individual will not perform the response until it comes time for reinforcement to occur again. This creates a “scallop-shaped” response (see Fig. 3).

In a *variable-interval schedule*, a behavior is reinforced based on varied amounts of time. It is unpredictable, so an individual can never be sure when the reinforcement will be delivered. A professor may deliver pop quizzes on a variable-interval schedule by giving the quizzes at unpredictable times. During 1 week of class, students may take two quizzes. On other weeks, there may be no quiz at all. This reinforces students to study because they will not know when they will have a pop quiz. The rate of responding in a variable-interval schedule is moderate but constant. The students will likely not study the way they would for a large exam the next day.

There is typically very little pause after reinforcement is given.

A *fixed-ratio schedule* means that reinforcement is delivered after a certain number of responses. A student earns allowance from her parents for every five homework assignments that she completes. Fixed-ratio schedules promote quantity of response, meaning this student will be likely to do her homework every single night. However, she may not work hard and receive a failing grade on all of them, because the quality of her response is not promoted. A fixed-ratio schedule results in a high, consistent response rate until the reinforcement is delivered. After the reinforcer is administered, there will be a pause in responses before responding resumes.

In a *variable-ratio schedule*, the reinforcement is delivered after a varied number of responses. This schedule creates the highest and most consistent rate of responding of any of the reinforcement schedules. The animal cannot predict when the reinforcer will be delivered. An example of this is the way that slot machines operate. A slot machine operates on an unpredictable win schedule, but players know that eventually there will be

**Behaviorism,**  
**Fig. 3** Schedules of  
reinforcement

a payout because there is a constant probability of hitting the jackpot. Players hesitate to stop playing at the machine even after continual losses due to the possibility that the next game will be a winner.

### Extinction

Of course, an individual would not sit at a slot machine forever on the expectation of winning if there was never any reward. In Skinner's autobiography, he told the story of how he discovered extinction in the operant conditioning paradigm. Though much of Skinner's experiments were performed with intention, he found extinction through an accident in his laboratory. A rat was in a Skinner box, pressing a lever for food pellets when the pellet dispenser broke. The rat continued to press the lever for pellets, but no pellets came (thus, the rat was not reinforced for pressing the lever). Soon, the rat stopped pressing the bar in the same way that Pavlov's dogs stopped salivating to the sound of a metronome when no food was delivered (Pavlov 1927; Skinner 1979). Both responses, the lever-press and the salivation response, were extinguished through *extinction*. Extinction is when a behavior is no longer reinforced (the lever-press stopped delivering pellets), and so the response decreases until it stops (the rat stopped pressing the lever; Skinner 1938).

When a behavior no longer leads to reinforcement, there is sometimes an increase in the target behavior before there is a decrease. This is referred to as an *extinction burst*. There may be new behaviors that accompany the increase behavior. A child throwing a tantrum in the store may scream louder or drop to the floor and roll around, all behaviors in escalation of their original tantrum behavior. The extinction burst serves a behavioral purpose. A behavior that has previously produced rewarding consequences might still have a chance of producing a rewarding consequence.

### Differential Reinforcement

To increase target behaviors while decreasing other target behaviors, simple schedules of reinforcement and extinction are used together in differential reinforcement procedures. *Differential reinforcement of alternative behavior (DRA)* decreases an undesirable behavior through extinction

(or, less commonly through punishment) while reinforcing an alternative response (Miltenberger 2008). An example of DRA is when a parent ignores their screaming child and only responds when the child uses calm coherent words.

*Differential reinforcement of other behavior (DRO)* is also referred to as "omission training." This is when a positive reinforcer is only delivered (and delivered periodically) when a subject engages in something besides a target response (Miltenberger 2008). A child with a nail-biting habit can be reinforced when he does anything with his hands besides biting his nails, such as clapping or keeping his hands in their lap.

*Differential reinforcement of incompatible behavior (DRI)* decreases an undesirable behavior through introducing a competing behavior. Both behaviors cannot occur at the same time, and the competing behavior is reinforced instead of the undesirable behavior (Miltenberger 2008). Owners who are teaching their dog not to jump on guests should have the guests ignore the dog when it jumps on them. When all four of the dog's feet are on the ground near a guest, he can be provided with reinforcing pats on the head or treats. The dog cannot engage in the jumping behavior and the standing behavior at the same time.

### Shaping and Chaining

Many individuals who are handicapped rely on a service dog for assistance. The dog may perform tasks that the person is not mobile enough to complete without help, such as loading the laundry machine. But, a dog does not understand how to do laundry nor can a dog comprehend verbose instructions. Likewise, the process of loading a laundry machine is far more complicated than a simple command (such as "sit" or "stay"). The seemingly monumental task of teaching a service dog can be approached through *shaping*. Shaping is defined as differential reinforcement of "successive approximations" that will eventually lead to the full response (Skinner 1953). At first, the dog may be reinforced every time he looks at a sock. Then, he will be reinforced any time he looks at a sock and also steps toward it. The dog should no longer be reinforced for simply looking at the sock. Through the use of shaping these successive

approximations, the dog will eventually be able to pick up the sock.

Another reinforcement technique that may need to be used for this dog is *chaining* or the process of linking behaviors together so that the result of each behavior becomes the stimuli for the next behavior (Skinner 1934). The dog may be taught to pick up the sock and then bring the sock near the laundry machine. Once the dog has successfully picked up the sock and brought it to the machine (the first and second behaviors in the chain), the dog can be taught to drop the sock into the laundry machine. The desired behavior can be taught as an entire series with specific prompts for each step in the chain (e.g., the dog picks up the sock with its mouth, walks to the washer machine, stands up on his hind legs, opens his mouth, and drops the sock into the washer machine).

### Applied Behavior Analysis

Skinner boxes are an effective way to reinforce one rat at a time, yet the external world does not tend to isolate an individual for behavioral observation. The principles of Skinnerian behaviorism and radical behaviorism serve as the foundation to the field of *applied behavior analysis* (ABA). The difference between ABA and operant conditioning exists in examining the function of a behavior in the environment and developing systemic interventions to modify behavior. The first “A,” *applied*, is a focus placed on the social significance of the behavior, taking the behavior out of a “box” and placing it into the environment. The behavior must be observable for objective measurement. The last “A,” *analysis*, indicates that behavior must be measured in ways that demonstrate the impact of the environment. An effective behavior analyst should have an understanding of the environmental settings that make an organism engage in a behavior (Baer et al. 1968).

Success has been gained through the use of the principles of applied behavior analysis in reinforcing target behaviors in a larger population. Specifically, *token economies* can reinforce specific target behaviors on a large scale with many individuals in a system (such as students in a school or inmates in a prison). Tokens are

provided as a secondary reinforcer and can be exchanged for desirable items. These may be tallied as points, kept on a chart, or distributed as physical currency. The tokens are provided when a desired target behavior is performed and can be distributed by teachers or correctional officers. For example, tokens can be administered at a school when a student clears their tray at lunch. Other students will be motivated when they see the first student earn a reward. The tokens can be exchanged in a “store” for backup reinforcers, such as toys, food, or passes for leisure time (items that “back up” the tokens and give the tokens value). Token economies are effective in increasing target behaviors when the tokens are provided consistently and immediately in response to a target behavior. Though token economies are not transferable out of a closed system into the open world, they can effectively target and change behavior within the system.

### Skinner’s Philosophy of Behaviorism

It is important to note that many individuals view radical behaviorism as a means to predict all behavior of all organisms. This suggests that organisms do not have any true free will and that all sequences of behavior are inevitable. The philosophy that all behaviors are predetermined is referred to as *determinism*. Skinner openly stated that he believed free will to be an illusion, because operant conditioning suggests that consequences are predictable. An organism will engage in specific behaviors depending on the environment in which the organism exists (Skinner 1974). Skinner also stated that it would be nearly impossible to map out every behavior in which an organism would ever engage (Skinner 1938). Since it is impossible to identify all the variables determining a target behavior, the adoption of a fully deterministic approach can appear extreme. Yet, one can still support determinism while understanding that it is impossible to know all the predictor variables and their value to the organism.

Skinner believed that there was a definition of freedom that was still in line with the deterministic approach. He argued that empowering individuals was a useful tool to incite rebellion against oppressive political authorities. Yet, he pointed

out how these overcontrolling authorities were only in power due to the government that humans built. The freedom that Skinner supported was to submit to the forms of control that are the most scientifically effective, opposed to maintaining a façade of autonomy under self-imposed political oppression. Along with reshaping freedom, Skinner rejected the notion of dignity or the idea that individuals deserve credit or punishment for their behaviors. He suggested that society does not provide credit to those who behave under duress or control and that there are forces in control of all individuals (Skinner 1971). In this view, individuals do not act creatively upon their environments and should not be rewarded as if they do.

The publication of Skinner's novel *Walden Two* (Skinner 1948) brought his idealistic sociopolitical worldview into prose in a fictional utopia founded on behaviorism. He spoke of learning incentives that could contribute to human happiness while reducing systemic injustice and power imbalances. The fictional society *Walden Two* is built on a program of behavioral engineering that begun at birth for all members that makes individuals motivated and cooperative. Man is assumed to not be autonomous. There is a community-based governance that is modified with empirical evidence at the heart of *Walden Two*, with no governing body. Individuals engage in work simply because they enjoy contributing to the community. Personal expressions of gratitude toward other individuals are outlawed, as this supports the idea of dignity. Skinner described the citizens of *Walden Two* as harmonious and happy, though only provided a foggy description of how their daily lives functioned. He gave no discussion on how interpersonal conflict or differences could be resolved. Nonetheless, the theoretical society gave Skinner a platform to put his behaviorism into a context where a system of reinforcement could produce all of society's advances.

## Sociobehaviorism

Despite Skinner's beliefs, not everyone believed reinforcement and associations could account

for all learning. Albert Bandura, a professor at Stanford, is most recognized for proposing how social interactions lead people to learn new information. He believed learning could occur through *modeling* (aka *observational learning*), watching someone else perform the behavior (Bandura 1986). Bandura posited that most learning is achieved through modeling, and at times learning can only be achieved through modeling. A medical student does not learn about surgical procedures by practicing on patients but instead watches an accomplished surgeon perform the procedure. Bandura expanded his work into a theory known as *social learning theory*, which became the cornerstone of sociobehaviorism.

There are three tenets of social learning theory: (1) People learn through observations (modeling). (2) Internal mental states are an integral component of observational learning. (3) A new behavior can be learned, but it does not mean the person will perform the behavior. Bandura changed the name of social learning theory to *social cognitive theory* to stress the importance of internal mental states, deviating from typical behaviorist ideals.

## Reciprocal Determinism

Social cognitive theory proposes a *continuous, dynamic* relationship with personal factors, environmental factors, and behavior, known as *reciprocal determinism* (Bandura 1986). These three factors do not equally influence behavior, but rather the factors' influence varies based on context. Personal factors include cognition (e.g., expectations and self-judgments), self-efficacy, motivation, and personality. As stated above, Watson and Skinner did not account for these factors. Bandura believed self-efficacy greatly impacts behavior as individuals with higher self-efficacy, the degree to which an individual can master a skill, are more likely to have confidence in their abilities and thus behave differently than those with low self-efficacy. When an individual believes a behavior will be effective, their motivation to perform the behavior increases. If the behavior *is* effective, the individual may be rewarded through *intrinsic reinforcement* (e.g., pride, satisfaction, sense of accomplishment) or if the behavior is ineffective, the individual may

be punished through *intrinsic punishment* (e.g., disappointment, shame, guilt).

Environmental factors include the situation, models, relationship to the models, roles, as well as reinforcers and punishers. As discussed above, the environment may reinforce or punish a behavior, which is likely to impact the behavior re-occurring. A model demonstrates how to perform the behavior. The model and the individual's relationship to the model can alter how quickly the individual learns the behavior. Placing importance on self-efficacy, Bandura believed that the environment should improve self-efficacy to motivate the individual to perform the behavior.

The third factor is behavior, and it includes knowledge, complexity, duration, and skill of the behavior. The knowledge of the individual and the complexity of the task influence the motivation of the individual to perform the behavior. In addition, the individual's skill level influences how well the individual thinks he will perform on the task, which relate to low self-efficacy. When an individual has low self-efficacy, he is less likely to perform the behavior.

As mentioned above, Bandura believed that all three of these factors (personal, environmental, and behavior) influences behavior. An example of how all three factors influence one another is when a father teaches his son how to hit a baseball. The son first watches the father (model) swing the bat (environmental factor). The son then

thinks he is able to swing the bat the same way (personal factor) and models his father's behavior (behavior). The father then rewards his son by saying "good job" (environmental factor). This increases the son's self-efficacy (personal factor), which means the son is more motivated and thus more likely to believe he can swing the bat, increasing this behavior (behavior) (Fig. 4).

### Observational Learning

As seen in Bandura's concept of reciprocal determinism, social interactions influence behavior. Bandura emphasized how observing another perform a behavior can lead to a change in behavior. He first noticed this in his classic studies known as the *Bobo doll experiments* (Bandura 1965; Bandura et al. 1961, 1963). He had children watch adults either aggress (verbally and physically) on or ignore a clown toy called a Bobo doll. The children who saw the adults act aggressively were more likely to aggress (verbally and physically) on the Bobo doll. Bandura found that while watching the adults aggress was important, the sexes of the adults and children played a role as well. The boys watching adult males physically aggress on the Bobo doll were the most likely participants to imitate physical aggression. Interestingly, Bandura found that girls who witnessed adult females verbally aggress on the Bobo doll were most likely to imitate verbal aggression (Bandura et al. 1961). This led Bandura to

**Behaviorism,**  
**Fig. 4** Reciprocal  
determinism

conclude that humans learn through observations and that the characteristics of the model are also important.

The second Bobo doll experiment reemphasized that a model's characteristics are important (Bandura et al. 1963). Bandura stated that there are three basic models of observational learning: live, verbal instructions, and symbolic model. Live observational learning is watching the model perform the behavior in vivo. Verbal instructions are when the observer reads a description of the behavior. Symbolic models are real or fictional characters performing a behavior in other forms of media (e.g., books, movies, television programs).

Bandura (1965) built on the previous Bobo doll studies by examining how children reacted when they watched a video of a model aggress on the Bobo doll and the model was either reinforced (given candy), punished with the warning, "don't do it again," or experienced no consequences. Bandura found that children who were shown a video where the physical aggressor was punished were less likely to be aggressive. The next phase of the study asked the children to imitate the behavior they saw on the video. The children were able to accurately imitate the behavior, showing that reward and punishment do not influence retaining information, but rather, only if the behavior is demonstrated. This is a core concept of social cognitive theory, emphasizing how a behavior can be learned but not performed due to the individual's lack of motivation, not lack of knowledge.

There are four steps the observer must engage in for the model to effectively transmit the information: attention, retention, reproduction, and motivation (Bandura 1986). The observer must pay *attention* to the model to process the information. There are several factors that influence attention: accessibility, relevance and complexity of the task, functional value of the behavior, as well as the observer's characteristics – cognitive capability, values, preconceptions, emotional arousal, and self-efficacy. In addition, accessibility is influenced by how much the observer identifies with the model and the observer's expectations of the behavior. *Retention* is the observer's ability to

remember how the behavior was performed, as well as the result of the behavior (i.e., reinforced, punished, or neutral). It may involve the individual mentally reenacting the behavior. The third step is physically *reproducing* the behavior so that it leads to skill advancement and improvement. This step may also include feedback from individuals, including the model. The last step is *motivation*. The observer learns the skill by the reproduction phase but must be motivated to perform the behavior. Two factors that affect motivation are vicarious reinforcement and intrinsic reinforcement. If the observer sees the model reinforced for their behavior, the observer has increased motivation to perform the behavior. This is known as *vicarious reinforcement*. Even though the model was reinforced, vicarious reinforcement leads to a positive emotion for the observer as he is excited about the potential of receiving the reward. If vicarious reinforcement is not experienced, the observer may learn the behavior, but may not be motivated to perform it, relating back to the third concept of social cognitive theory mentioned above. Also mentioned above, motivation may increase based on intrinsic reinforcement (e.g., pride, satisfaction, sense of accomplishment), leading to the production of the behavior.

### Outcome Expectations and Self-Efficacy

After watching the model perform the behavior and seeing the result (i.e., reinforcement, punishment, or neutral), the individual begins to develop expectations of the outcome. The individual does not necessarily believe that the *same* reward or punishment may occur but recognizes that behavior is context dependent and instead a *similar* outcome will occur. *Outcome expectations* (Bandura 1986) are an individual's predictions about the functionality of a behavior and how the environment will respond to the behavior. Bandura believed that outcome expectations along with efficacy judgments are the *best predictors* of behavior. If an individual has high outcome expectations and efficacy judgments, he is more likely to engage in the behavior. *Efficacy judgments* (Bandura 1986) are the individual's appraisals of how well he can perform the specific

behavior. For example, a child learning to read may be reinforced for every sentence he reads correctly (outcome expectations). However, the child may not believe he can read even three words correctly (efficacy judgments) and, therefore, may not read. Generalized efficacy judgments directly relate to *locus of control*. Rotter (1966) explained locus of control as the extent to which one believes he has control over the situation. The spectrum of locus of control ranges from internal to external. An example of complete internal control is the individual believing that he has absolute control over the outcome. Complete external control is the individual believing that he has no control over the outcome.

These cognitions (outcome expectations, efficacy judgments, and locus of control) relate to self-efficacy (Bandura 1986). As mentioned above, self-efficacy is the individual's belief that he can master a skill. Self-efficacy affects how goals, tasks, and challenges are approached. If an individual believes he can perform the behavior well and produce a positive effect, he is more likely to behave. If the individual does not believe he can perform the behavior well and/or produce a negative effect, then he is less likely to engage in the behavior. Bandura found that individuals with high self-efficacy are more likely to model behaviors than individuals with low self-efficacy. He credited this finding to the belief that individuals with low self-efficacy believe they will not perform the task well and thus avoid the tasks.

Bandura (1986) believed that increasing an individual's self-efficacy could produce therapeutic effects, such as the individual having a more positive affect and produce more functional behaviors. Bandura presented three ways self-efficacy could be increased: mastery experience, social modeling, and improving physical and emotional states. *Mastery experience* has the individual focus on simple tasks that are easy to achieve, gradually increasing to more complex tasks. This increases the individual's efficacy judgments, which increases their motivation to perform the behavior. *Social modeling* is having the individual participate in observational learning. An individual with low self-efficacy can develop it by paying close attention to a model's behavior. Compared

to the individual with high self-efficacy, Bandura believed that the individual with low self-efficacy may need to watch the model perform the behavior more often. This is not because he does not retain the information but rather because he does not *believe* he retains the information and/or will not be effective. Bandura (1986) also emphasized *improving physical and emotional states*. An individual who is stressed is less likely to believe he can effectively perform a new behavior, compared to an individual who is rested.

Bandura's social cognitive theory is one of the first behavioral theory focusing on cognitions. He described how the environment, behavior, and the personal factors (e.g., cognitions) dynamically influence one another. He called into question Skinner's claim that reinforcement and punishment can account for all learning; instead, Bandura believed that observational learning accounted for more learning than operant conditioning did. Social cognitive theory's addition of cognitions addressed the growing disconnect of research showing thoughts can influence behavior.

## Conclusion

Behaviorism rose from rebellious beginnings as an alternative movement in a world of unobservable psychology. With the rise of behaviorism, mentalistic approaches toward patients became outdated. However, the latter half of the 1900s marked a time for psychology to change again, with a new focus on the importance of cognition. Noam Chomsky, a linguist, philosopher, and cognitive scientist, wrote a review of Skinner's work that served as a call to arms. Chomsky did not deny the points that Skinner made but argued for the importance of examining higher mental states. Specifically, Chomsky believed that language acquisition could not be explained through traditional behaviorist belief (Chomsky 1959). Thus, the cognitive revolution began, though behaviorism was not forgotten. As Bandura expressed through his social cognitive theory, the two could be blended effectively into a new paradigm. In 1986, Clark noticed that cognitive misinterpretations of physical sensations would cause patients

to catastrophize symptoms of anxiety (e.g., “I am having a heart attack”), causing panic attacks. He posited that there was merit to treating the cognition that maintained the behavior (Clark 1986). Thus, came the beginnings of cognitive behavioral therapy. Cognitive behavioral therapists hypothesize that the activating events lead to cognitions that then affect one’s behavior. These cognitions are treated as new stimuli and new responses in the stimulus and response chain. Behavior therapies placing an importance on thought and internal experiences created a well-rounded therapeutic orientation that allowed for patients to express their thoughts and feelings while also implementing behavioral change (Rachman 2009).

Modern therapeutic application of behaviorism calls for clinicians and patients to work together in addressing, and ultimately changing, behaviors that interfere with the patient’s functioning. The tenets set forth in Watson’s writings transformed psychology into a science. Behaviorism values observation over assumption in research and behavioral change over mentalistic introspection in therapeutic practice. New waves of behavior therapies are created, researched, implemented, and popularized in cycles. Yet, they all build off the foundational underpinnings that were laid out by the forerunners of behaviorism.

## Synonyms

Aggressiveness; Anger; Hostility; Impulsivity; Violence

## Definition of Aggression

Within psychological literature, aggression is defined as any behavior that intends to cause harm (Stanford et al. 2003). The intentionality of aggression is a key consideration of the definition. As such, an automobile accident that results in a passenger having a broken bone or a dentist drilling a tooth to fill a cavity and causing residual pain would not be considered aggressive acts. Aggression itself can be experienced as an overt act (e.g., hitting, kicking, punching) or covert act (e.g., spreading of malicious rumors, bullying, or intentional social exclusion; Yamasaki and Nishida 2009).

## Introduction

The following is a summary of the current aggression literature. It provides a framework by which to understand the benefits of human aggression, as well as the limitations of historic models. Specifically, this entry outlines current definitions of aggression and theoretical models by which current aggression literature is conceptualized and ends with the consideration by which aggression can be seen as evolutionarily beneficial.

## Categorizations of Aggression

The extensive exploration of aggression in research literature resulted in the categorization

## Benefectance

### ► Self-Serving Bias

of aggression in three distinct ways: reactive-inexpressive, reactive-expressive, and proactive/instrumental (Yamasaki and Nishida 2009).

### Reactive-Inexpressive

Reactive-inexpressive aggression, also referred to as hostility, is aggression that is often expressed without clear reason or purpose. This typically occurs as a result of provocation or frustration and is evidenced as acts of impulsivity (e.g., an infant crying and flailing its limbs as a result of being restrained). In a study of peer relationships among school-aged children, those children displaying reactive-inexpression aggression were found to have fewer friend groups (Yamasaki and Nishida 2009). Within most cultures, reactive-inexpressive aggression is regarded as primitive and erratic and, as such, is often stigmatized (Campbell 1999).

### Reactive-Expressive

Reactive-expressive aggression encompasses overtly aggressive acts – namely verbal aggression and physical violence – in response to environmental and personal triggers. The interaction of frustration and provocation has been shown to shape these responses (Bandura and Walters 1977). Additionally, an individual's emotional state and perception of unfolding events also contribute to the likelihood of displaying reactive-expressive aggression (Dodge 1996).

### Proactive/Instrumental

Although proactive aggression may include a verbal component, the primary difference of this model is that the aggression is deliberate and is used to accomplish a specific goal (Stanford et al. 2003). By way of spreading rumors, this type of aggression occurs in order to manipulate social networks, break human relationships, and/or ostracize targets from their peers (Yamasaki and Nishida 2009). Proactive aggression can be used to obtain a goal other than injury to a target, but aggressors in this model willfully cause harm to specific targets in the pursuit of that goal (Bushman and Anderson 2001).

## Sex Differences in Types of Aggression

Early aggression research largely focused on overt physical aggression as opposed to indirect and relational aggressive measures. As such, the field largely indicates males to be more aggressive than females (Bettencourt and Miller 1996).

Currently, more comprehensive research has now found that each sex tends to favor different forms of aggressive behavior with most males resorting to direct aggression (usually reactive-expressive) and females tending to use indirect aggression (proactive/instrumental) (Campbell 1999; Björkqvist and Österman 2018). This is frequently hypothesized to stem from physical differences between the sexes (i.e., men are usually larger and stronger than women, making personal injury more likely) as well as the stigmatization of outwardly aggressive women (i.e., as “irrational” or “crazy”) (Campbell 1999). Further, there is evidence that, whereas male aggressive patterns are relatively stable throughout formative years, female children exhibit less physical aggression (replacing it with verbal aggression) as they get older (Österman et al. 1998).

## Theories of Aggression

### Instinct Theories

*Psychoanalytic theory (1927).* One of the oldest theories on aggression belongs to Freud. The psychoanalytic theory posits that humans possess an internalized death instinct (Thanatos) that propels them toward death and underlines all acts of violence. This instinct can be redirected externally through socially appropriate means (e.g., vigorous or high energy work or play) or via less desirable means (e.g., disparaging others, physical confrontations, and/or destruction of property). Aggressive urges can also manifest internally via self-harm, mutilation, or suicide (Steiner 2009). Within this model, physical aggression is seen as the release of violent forces intrinsic to the human condition.

*Ethological Theory of Aggression (1966).* Another theory, by Konrad Lorenz, also views aggression as instinctual but postulates that aggression is an intrinsic survival instinct. Lorenz

presents an ethological model of human aggression, citing resource competition among males in a variety of species. Lorenz visualizes aggression as a force that builds up and motivates the host organism (humans) to behave outwardly aggressively as a means of survival (Lorenz 2002).

While both Freud and Lorenz present aggression as an internal human force, Freud believes aggressive forces are inherently self-destructive. Conversely, Lorenz holds that aggression is an internal survival instinct. He argues that physical aggression is essential for self-protection, resource control, and continued survival within a hostile world.

### Social Learning Theories

*Bandura's Social Learning Theory (1973, 1989).* Bandura's social learning theory suggests that children learn aggressive behavior by observing models (parents, peers, any person they see in media or in the physical world). According to Bandura, children are primed to behave aggressively by witnessing aggressive acts, either in person or through media. One experiment ("Bobo the Doll") clearly illustrates these effects: 5- to 6-year-old children watched a video of an adult playing with a Bobo doll (a large, inflatable, and weighted doll) either violently or nonviolently. After watching the video, the children in the study were allowed to play with the doll unsupervised. Children were likely to repeat the actions they saw modeled by the adult in the video, suggesting that individual behavior is influenced by direct observation, reward, and punishment (Bandura and Walters 1977).

*Dodge's Social Information-Processing Theory (1994).* Crick and Dodge's social information processing model explains how aggressive behavior could develop in children. Their model recognizes reactive and proactive aggression and holds that children pass through five cognitive stages that may allow them to rationalize and further support their aggressive behavior. The stages are as follows: encoding of social cues (evaluating offender's reaction to the offense), interpretation of cues (deciding whether the offense was intentional), response access (possible reactions), response evaluation (possible outcomes and

relation to desired outcome), and response enactment (aggressive or nonaggressive action) (Dodge 1996).

### Cultural Interpretation or Display of Aggression

Societal factors affect aggressive displays and their interpretation. In the United States, a study by Condry and Ross (1985) evaluates the influence of gender on participants' views of aggressive behavior. In the experiment, participants are asked to watch a video and rate the aggressiveness of two children playing together. In the video, the sex of the two children is impossible to discern due to the thick snowsuits they are wearing. Viewers are given varying sex information about the children dyads (male-female, male-male, female-male, female-female) as they engage in "rough and tumble" play. The findings indicated that most individuals rated the play to be more aggressive when viewers believed the antagonistic child was female. Conversely, the results indicated the assignment of lower aggressiveness scores for the exact same video when participants were told the two children playing were males. This study suggests a cultural expectation and acceptance of aggressive play specifically by males, a "boys will be boys" mentality.

Further illustrations that culture influences aggression can be found in a cross-cultural study by Forbes et al. (2009). In their sample, they found that individualistic societies tended to exhibit aggression more frequently than collectivistic ones. It is worth noting that, in these studies, females used indirect aggression more frequently than males, although males were observed to be more aggressive overall than females. This relationship held constant across the three countries observed in the study.

### Physiological Differences in Aggression

#### Brain Activation and Hormones

Aggression is shown to activate neural pathways within the amygdala. This portion of the brain is

also associated with anxiety and defensive behavior (Craig and Halton 2009). Brain scans reveal heightened activation of the amygdala in very aggressive subjects compared with nonaggressive subjects (Nelson and Trainor 2007).

The hormone oxytocin plays a role in human defensive aggression: Oxytocin has long been linked to bonding and commitment, especially regarding human mothers and their offspring. However, oxytocin has also been found to increase a mother's likelihood to respond aggressively to external threats against her children (Campbell 2008).

The prefrontal cortex of the human brain helps restrain aggression; as such, damage to this region has been associated with increased aggression (Nelson and Trainor 2007). Specifically, the amygdala plays a significant role in aggression and emotional processing and is most responsive to fearful facial cues (Davidson et al. 2000).

Pheromones, found in humans and animals, are also thought to contribute to aggressive interactions. Specifically, androstenol (a human pheromone released by males via sweat glands) was shown to affect women during their monthly cycle, causing them to report feeling more submissive (Benton 1982). Other studies have shown that, during their monthly cycle, heterosexual women are more likely to desire sexual relations with more aggressive mates. This tendency is negated when women take birth control pills that suppress menstruation (Lehmiller 2017).

## Socioeconomic Status and Aggression

Just as cultural norms and social cues affect interpretation and display of aggression, an individual's socioeconomic status (SES) is also indicative of the types of aggression likely to be employed. Specifically, higher SES individuals are more likely to use proactive and reactive aggression to accomplish social goals, whereas lower SES individuals are more likely to use physical aggression (Baş and Yurdabakan 2012). Research indicates an overall inverse relationship between aggression and SES that goes beyond the display of specific aggressive styles: Low SES

individuals are likely to score higher on willingness to use aggressive measures than higher SES individuals (Letourneau et al. 2013).

## Benefits of Aggression

Consideration of the aggression literature with a focus on competition helps illustrate the benefits of aggression – especially in ritualized customs like organized sports (Bushman and Anderson 2001). Obvious benefits of aggression include the following: enabling cooperation, fostering in-group loyalty, pooling of resources, defense against attacks, deterring future aggression, status negotiation within a group hierarchy, and deterring sexual infidelity by childrearing partners (Buss and Shackelford 1997). The importance of shared social communications is important, as aggressive displays intended to intimidate and circumvent conflict will not have the desired effect if both parties do not interpret the aggressive signals in the same way. An observable case of social differences in content and context of aggressive displays failing to prevent violence is the 1991 meeting between Iraqi and US officials to resolve a conflict in Kuwait. While the US representative was verbally aggressive, the Iraqi representative did not believe the validity of the message because it was not delivered with the expected physical display of aggression (e.g., shouting, striking surfaces with a fist, and throwing an item in anger; Triandis 2000).

## Procreation

Previous literature has documented that females responding aggressively to provocation and maternal aggression is a clear benefit to otherwise vulnerable children (Campbell 1999). Interestingly, evidence suggests that, while actively breastfeeding, human mothers behave more aggressively to provocation, compared with control subjects who were provoked while bottle-feeding their children (Hahn-Holbrook et al. 2011).

While aggression has been linked to genetic markers, research has indicated that situational factors are known to activate (or suppress) the expression of particular genetic traits. Further,

both biological and environmental influences appear to equally influence a child's development of aggressive tendencies, but in adulthood, hereditary inclinations appear to be stronger (Craig and Halton 2009).

### Animal Studies of Aggression

Within animal cohorts, males are usually more physically aggressive than are females. It has been postulated that aggression is largely influenced by androgens (e.g., testosterone). Test results from these and other studies are not conclusive: Mice displayed increased aggression after being injected with testosterone. A study conducted by the same researchers the following year received the same results after injecting the rats with estrogen. Researching at the human level, four independent studies were conducted injecting androgens into human males; only one study found a resulting increase in aggressive behavior (Björkqvist 1994).

Lab experiments removing the male-determining gene from Y chromosomes in rats yielded subjects that still exhibited aggression, indicating that other genes on the Y and X chromosomes also influence aggression (Craig and Halton 2009). Research involving mutated mice lacking androgen receptors indicates that mice lacking these receptors are not aggressive (Nelson and Trainor 2007). Although it appears to have not been tested, hormone sensitivity (specifically testosterone) could be a significant factor in the level of aggression displayed by individuals. The neurotransmitter serotonin has been linked to emotional regulation and aggression – particularly when the serotonin supply is disrupted (Davidson et al. 2000).

Situational conditions also affect animal aggression, particularly stress. Mice were found to be more aggressive after periods of physical restraint (this effect was replicated in dogs by restricting their spatial views) and more likely to aggress (even against larger opponents) after winning a series of fights. However, mice were found to be less aggressive after losing multiple aggressive encounters, even when confronted with smaller and weaker opponents (Sandi and Haller 2015).

Resource competition, especially fertile mates, often require increased aggression. Among the very aggressive elephant seals, 5% of the population's males sire 85% of the offspring conceived during the mating season (Buss and Shackelford 1997).

### Conclusion

The aggression literature reveals an intricate patchwork of research findings. Indeed, environmental and genetic factors only further establish the complexity of studying aggression. Our current understanding of the field (i.e., theories, contexts, sociocultural factors, brain activation, etc.) is established as a result of the combination of extensive human and animal studies. While often associated and portrayed as a negative quality, aggressive behavior on its own may not be overwhelmingly negative. In fact, several research studies display benefits of aggressive behavior.

## Bennett G. Galef

David J. White

Department of Psychology, Wilfrid Laurier  
University, Waterloo, ON, Canada

Bennett “Jeff” Galef, Jr., was born on May 23, 1941 in New York City. After receiving his BA in Psychology from Princeton University and his MA and PhD in Physiological and Comparative Psychology from the University of Pennsylvania, Jeff migrated north to McMaster University in Ontario, Canada, and began a remarkably productive career studying Animal Behavior. Like many classically trained experimental psychologists at the time, Jeff’s research interests focused on feeding behavior. His work, however, departed significantly from psychological traditions in two important ways. First, it was highly integrative. Inspired by Daniel Lehrman, the great Comparative Psychologist, and Niko Tinbergen, the equally great Classical Ethologist, Jeff merged the strengths of these disciplines into his research program, allowing him to be able to think meaningfully about the mechanisms and development of feeding behavior along with the ecology and evolution of foraging. While such an integrative approach to studying behavior has long been considered the ideal for animal behavior research, few research programs have been able to integrate all of these levels of analysis so seriously and successfully as has Jeff’s.

Jeff’s second departure from classical experimental psychology was to study how social behavior plays a role in food and foraging site selection. Jeff was one of the first to realize that social factors were critical to foraging decision processes. Up to this point, social factors were

typically considered to be noise variables that needed to be removed from study. In contrast, Jeff set out to devise a means to study social influences on behavior while maintaining exacting standards of experimental control. The consequences of this work were effectively to create a new field of scientific inquiry in biopsychology into the mechanisms and function of social learning, a field that is still of pronounced interest to this day.

Jeff sets out to answer a seemingly simple question: Why is it so difficult to get rid of rats? As any farmer with a rat infestation will explain, poisons are moderately effective at first, but become ineffectual very quickly afterward. Rats seem to learn to avoid the poisons. Jeff was determined to examine how this occurs working under the hypothesis that rats might learn from one another about what to eat and what not to eat. Jeff created an experimental procedure where a “demonstrator” rat who had eaten a food with a novel flavor would interact with an “observer” rat, who was naïve to the flavor of the food the demonstrator had previously eaten. After only a single, brief interaction with the demonstrator, the observer would reliably gain a strong and lasting preference for the food the demonstrator had eaten. Jeff had discovered that rats can indeed communicate about food preferences.

With effect (and new procedure (Galef and Wigmore 1983) in hand, Jeff conducted an extraordinary number of experiments designed to isolate the mechanism by which the social transmission of preference occurs. For example, he examined whether the observer gained a preference for the food if the demonstrator with whom she interacts was anesthetized (she did), or euthanized (she did not), or only dusted with food (she did not). Over the course of these and many more experiments, Jeff found that the mechanism that created the transmission of preference involved the observer smelling the food odors on the demonstrator paired with carbon disulfide – a volatile chemical in rat breath. Together, these odors are necessary and sufficient to provide an observer rat a preference for the novel food. In addition, Jeff discovered that there are myriad other social mechanisms that emerge throughout rats’ lifetimes (some of which start prior to birth) that

combine to give rats preferences for foods and foraging sites.

Ironically, after all of these experiments, the original question about how rats learn to avoid poison was never strictly answered. Rats do not seem to learn socially to avoid anything. The many redundant social learning systems function to give rats preferences for foods but not aversions. One of Jeff’s astute interpretations of this work is that ecology filters social information such that only information about good quality food sources ever returns to colonies. Rats with bad social information – those who have eaten poison – do not return to the colony (and do not produce carbon disulfide). Thus, all the information present in colonies on the breath of other rats is valuable information about good foods, and no social information exists about bad food sites. This leads rats to make complex, adaptive decisions about food with a relatively simple series of behavioral and cognitive mechanisms.

Even though Jeff is no longer studying the social transmission of preference system, his experimental procedure remains a highly popular model across many disciplines of science, including chemistry, neurobiology, endocrinology, social learning, and animal behavior.

While Jeff’s signature work has been on social learning in rats, he has also made important contributions to a wide variety of topics. His work with partner and collaborator Mertice Clark provided a classic demonstration of epigenetic transmission of acquired characteristics across development mediated by parental care (Clark and Galef 1994). He has studied bats, quail, wild rats, gerbils, agoutis, mice, jungle fowl, and fish and has even dabbled with humans.

The area of social learning in animals would arguably not exist today without Jeff. It certainly would not exist in its present form. He brought his highly exacting standards from his own research to the area and “encouraged” others to follow suit. He created consistent definitions, he set standards of evidence, and he provided a highly disciplined approach for interpreting results from experiments in the lab and field (Zentall and Galef 1988; Heyes and Galef 1996). The area is vibrant today, and hopefully researchers will continue to hold to these principles in the future.

In addition, Jeff has been a dedicated member of the community, serving on an extensive list of editorial boards and scientific committees. He has created conferences, has trained countless students in his lab, and is always available to assist, collaborate with, and give advice to young researchers. Speaking personally, I can attest to his tireless, rigorous, and caring support as a mentor.

Across his prolific career, Jeff sets the standard for the process of science. He has been awarded with numerous awards including the highly prestigious Fellowship of the Royal Society of Canada. Finally, Jeff is a Renaissance man. He has wide-ranging interests that include photography, chess, art, fly-fishing, and alpine skiing and is a consumer of fine sushi.

## Bernd Heinrich

Thomas Bugnyar  
University of Vienna, Vienna, Austria

## Introduction

Bernd Heinrich is a Professor emeritus in the Department of Biology at the University of

Vermont. He is internationally renowned for his pioneering work on insect physiology and behavior as well as on raven social behavior and cognition. He is also renowned for being an excellent field biologist, who is thoroughly testing the hypotheses derived from his observations, and a gifted artist and writer, who skillfully disseminates his findings to the scientific and lay audience alike. Bernd Heinrich’s major contributions to the fields of animal behavior, physiology, and evolution have been recognized via numerous prizes and awards, two honorary doctorates, and elected memberships in societies like the American Academy of Arts and Sciences.

## Heinrich’s (Unconventional) Life and Educational Background

Bernd Heinrich was born on April 19, 1940, in the area of today’s Poland as son of the zoologist Gerd Heinrich and Hildegarde. At the end of World War II, the family lived for several years as refugees in a cabin in the woods of Northern Germany before they emigrated to the United States of America in 1950. At their arrival, they were personally welcomed by the famous evolutionary biologist Ernst Mayr, who knew Bernd Heinrich’s parents as zoological experts and specimen collectors for museums. Bernd’s parents resumed work as collectors shortly after arriving in the USA.

Heinrich spent his high school and college years in Maine, graduating in Zoology at the University of Maine, Orono, in 1964 (BS) and 1966 (MS) respectively. He then moved to California, where he received his PhD in Zoology from University of California, LA, with distinction in 1970. Already a year later, he accepted a position at University of California, Berkeley. Between 1976 and 1977, he was a Guggenheim and Harvard fellow, and in 1978, he became Professor of Entomology in Berkeley. In 1980, he accepted a professorship at University of Vermont, where he was Professor of Biology until his retirement in 2004. In that time period, Heinrich was also in Israel, 1992 as Lady Davis fellow, and in Germany, 1988–1989 as an Alexander von Humboldt senior scientist fellow.

Heinrich has four children (Erica, Stuart, Eliot, Lena) and three grandchildren (Gabe, Liam, Mia). Upon his return to the east coast, he built himself a wooden cabin in the forests of Western Maine, which has served him as a field site and as a place of unlimited inspiration for his research ever since. Originally dividing his time between Maine and Vermont, he is now living permanently in a (newly built) cabin in the Maine woods together with his partner Lynn Jennings.

Aside biology, Heinrich's passion had been long-distance running. He holds world-records in ultramarathon distances for master runners and set American national records for any age in distances 100 km, 200 km, 100 miles, and longest distance run in 24 h. Due to these achievements, he was included in the American Ultrarunning Association's Hall of Fame. He also reflected on his favorite sport as scientist in his best-selling book "Why we run: a natural history."

## Scientific Career and Output

Bernd Heinrich can be characterized as evolutionary biologist and behavioral ecologist, who works on the interface between the field and the laboratory. Specifically, he is interested in physiological, behavioral, and cognitive adaptations to a species' environment.

Heinrich received international recognition for his innovative studies on insects, most notably for the discovery that sphinx moths maintain the same high body temperature during continuous free flight over a wide range of air temperature (Heinrich 1970). He then elucidated the physiological mechanism whereby this is accomplished, and followed with comparative studies over a wide range of other insects (e.g., Heinrich 1972, 1974). The thermal physiology studies of bumblebees were extended to their energetics and their foraging and learning behavior as a model for elucidating flower evolution (e.g., Heinrich and Raven 1972; Heinrich 1974, 1975). His studies on honeybees resulted in the discovery of how the thousands of bees in a swarm cluster regulate its temperature largely by individual initiative rather than communication (Heinrich 1981).

Heinrich is also famous for his work on ravens that got kick-started by the seemingly trivial observation of noisy crowds feeding at a moose carcass in Maine. Wondering how and why unrelated birds share information about food (Heinrich 1988), he was the first to reveal the complex pattern of cooperation and competition among nonbreeding ravens, providing experimental evidence for the active recruitment of conspecifics to overpower the food defense by dominants (Marzluff and Heinrich 1991). He then moved on to study raven "intelligence," a topic which had been present in the scientific literature for decades but almost entirely on an anecdotal level (he found >1000 anecdotes vs. 1 experiment in the mid-1990s). His pivotal studies on insight (Heinrich 1995) and knower-guesser differentiation (Bugnyar and Heinrich 2005) using the string-pulling and caching/pilfering paradigm, respectively, were highly influential for the emerging field of avian cognition.

Bernd Heinrich's scientific output contains numerous research papers (>70 on insects, >30 on ravens, many of them in top journals), semi-popular articles (>70), book chapters (>50), and award-winning books like "Bumblebee Economics" (1979), "Ravens in Winter" (1988), and "Mind of the Raven" (1999). Aside his main research topics, Heinrich has authored 20 books of natural history, almost all best-selling and award winning like the John-Burroughs-Medal for Nature Writing. Since retiring from the University of Vermont, he has published 24 nature essays as "Naturalist at Large" for Natural History Magazine, and 16 peer-reviewed scientific papers on various topics sparked by natural history observations where he lives in the Maine woods.

## Introduction

The formation of dominance hierarchies is a common feature in animals that live in group. In this kind of social organization, individuals are organized in ranks based in agonistic interactions to portioning resources among the group members. The dominant individual, the one that wins the fights over all other is called alpha. The second individual in the rank is the beta, the individual who loses fights with the alpha but wins over all others (Cafazzo et al. 2010). The beta animal will, most of the times, replace the alpha one when the alpha is no more considered the dominant for some reasons, as for example, when the dominant dies or when it is removed from the group (Whiteman and Côté 2004). Normally, beta is the rank position that receives more aggressive behavior from the dominant (Cafazzo et al. 2010), and defensive and submissive behaviors towards the alpha characterize the beta behavior. Towards other group members, beta is characterized by aggressive behavior.

## Best-Fit Models

### ► Model Fitting

## Beta

Daiani Kochhann  
Center of Agrarian and Biological Sciences, State University of the Acaraú Valley, Sobral, Ceará, Brazil

## Synonyms

Subdominant

## Definition

In a dominance hierarchy, beta is the individual that occupy the second position in the rank, just after the alpha.

## Advantages of the Beta Position

There are a lot of variable consequences of being beta, depending mainly on the species and on the social organization. Although most studies did not distinguish between beta and the other subordinates, we can observe some advantages of the beta position. When putting together to interact, alpha and beta mice did not lose weight, whilst subordinates do. Moreover, in more despotic groups, when alpha males are highly aggressive, subordinates have a lower testosterone level when compared to alpha and beta males, whereas testosterone of alpha and beta were indistinguishable (Williamson et al. 2017). In the passerine Taiwan Yuhina (*Yuhina brunneiceps*), alpha and beta males can sing the territorial song together, although the alpha male always sings more than the beta. Other subordinates (also called gamma) never sing in the presence of the beta or alpha. Furthermore, for females of the same group, although alpha tend to have higher number of laid eggs than beta, other subordinates did not reproduce at all (Yuan et al. 2004).

However, the most obvious advantages of being the beta is to get the alpha position when the alpha dies (e.g., in coyotes (*Canis latrans*, Gese et al. 1996) and in the male lance-tailed manakins (*Chiroxiphia lanceolata*, DuVal 2007)).

## The Beta Position and Stress

Besides to have some advantages, the beta position is still a subordinate position, and subordinate positions are, most of the times, associated with some level of stress. How stressful it will be to be subordinate will depend on the species and on the social characteristics of the group. Levels of cortisol, a physiological marker of stress, will be higher in subordinates when they (1) were subjected to higher rates of stressors, (2) experienced decreased opportunities for social (including close kin) support (Abbott et al. 2003), (3) are minimally related to other members of their social group, and (4) are in an enclosure too small to allow subordinate individuals to evade dominant ones (Sapolsky 2005).

## Conclusion

Beta individuals can be considered as the second-in-command or the highest rank subordinate. As in an intermediate position in the dominance hierarchy, it will have advantages and disadvantages depending on the species and, mainly, on the characteristics of the alpha and the group composition.

## Betta Splendens, the Siamese Fighting Fish

Kennon A. Lattal

Department of Psychology, West Virginia University, Morgantown, WV, USA

*Betta splendens*, more commonly known as the Siamese fighting fish or *Betta*, is a small (males, shown in Fig. 1, are around 6.5 cm long, females somewhat smaller) domesticated version of a fish native to small ponds and streams in what today is Thailand (Smith 1927). It is a member of the family Anabantidae. The *Betta* breathes by means of a lunglike labyrinth organ rather than gills. Through selective breeding over the last 110 years, the *Betta* has been transformed from a small-finned brown fish to one of the most visually and behaviorally striking of the so-called tropical fish. Both the domesticated male and female have bright iridescent colors, and the

(Photo credit: <http://www.animalsindetail.com/betta-fish-siamese-fighting-fish-betta-splendens/>)

male has long, flowing fins. It was first described in the scientific literature by Regan (1909) and introduced to the United States in 1927. It is a popular fish not only with amateur and professional aquarists but also with behavioral researchers. The latter's findings are the focus of this article.

The most conspicuous behavior pattern of either a male or female *Betta*, at least in the absence of a conspecific, is its periodic trip to the surface of the water, where it exchanges expired air for fresh air and then quickly swims to a lower level. The reason for this behavior is the breathing apparatus noted above; the fish must process air through lunglike structures rather than the gills that serve this function in most fish species. This breathing mechanism has been suggested to underlie the *Betta*'s reproductive behavior (Braddock and Braddock 1959). Unlike most egg-laying fish, male and female *Bettas* build their nests on the water's surface. The nests, appropriately called bubble nests, are composed of a conglomerate of mucous-covered air bubbles. To construct the nest, the *Betta* surfaces, gulps a mouthful of air, covers it with a saliva-like material, and extrudes it to the surface. The process repeats until several hundred bubbles are created and attached to one another. Both nest construction and egg production are optimal around 26.67 °C (Goodrich and Taylor 1934). Successful nests for raising fry are compact and

at least 6 cm<sup>2</sup>. Braddock and Braddock (1959) observed that almost all such successful nests were constructed by males.

Gravid females are treated quite inhospitably by male *Bettas*, at least by human standards. On entering the territory of a sexually receptive male, as indicated by the presence of a bubble nest, the male chases the female around the territory, nipping at her fins (which are far less pronounced than the male's) and sides for anywhere from a few minutes to several hours. Following this, the male wraps his body around that of the female and squeezes a few eggs from her ovum. Simultaneously he releases sperm cells into the water. He then releases the female, gathers the falling eggs into his mouth, and extrudes them into the bubble nest. This process repeats over up to several hours until all the eggs are ensconced in the bubble nest. The female plays no role in nesting, beyond providing the eggs (Braddock and Braddock 1959). The aggressive overtones of the sexual act are obvious in this description. In fact, females typically are injured and often killed as a result of a sexual bout with a male *Betta*.

*Bettas* exhibit a species-typical aggressive response pattern when they encounter a same-sexed conspecific. Although these attacks are more popularly associated with males, Braddock and Braddock (1955) observed fighting between 35 of 51 pairings of female *Bettas*. Of the two

sexes, the response of the male is the more intense, often being life threatening. Thompson and Sturm (1965, see also Simpson 1968) identified four distinct components of the *Betta*'s aggressive response: (1) frontal approach to the releasing stimulus, (2) fin erection, (3) gill cover erection/extension, and (4) undulating movements. In addition, there can be a darkening of color, and often dark vertical bands occur along the lateral side of the fish's body. The two fish then swim in parallel to one another for several minutes prior to the actual attack. Braddock and Braddock (1955) speculated that the preliminary display is critical in building to a threshold of aggressiveness, beyond which the actual attack is released. During the attack, fins and body are the most frequent targets, although damage to gill covers and eyes also occur. Attack and counter-attack can last from a few minutes to 3–4 h. There are anecdotal reports that fighting is suspended when the oxygen-deficient contestant breaks the encounter to replenish its oxygen supply. Visual stimuli are most crucial in releasing the aggressive response pattern, but other sensory modalities such as tactile and auditory stimuli also may be implicated (Evans et al. 1958). There is some variation in both the probability and intensity of aggressive behavior of male *Bettas*, but the aggressiveness of individual fish seems to be rather stable over time (Bronstein 1994). In general, the larger of the two fish usually is the winner (Braddock and Braddock 1955; Evans et al. 1958). Because of such aggressive attacks, it is usual to house *Bettas* separately from one another, although tropical fish hobbyists often house females together in community tanks without evoking serious attacks.

The aggressive display of both male and female *Bettas* also can be released by the presentation of visual images resembling another *Betta*. These visual images have included models of a *Betta*, photographs, video clips, and still photographs of a conspecific, as well as mirror images of the fish itself. Between 15 °C and 35 °C, the strength of the aggressive display depends on the water temperature and the degree of similarity between the visual image and a live *Betta* (Hess 1953). The aggressive display of *Bettas* habituates with repeated exposure to either a

conspecific or to a visual image of a conspecific (e.g., Clayton and Hinde 1968), exemplifying an elementary form of learning. As such, it has been the focus of a good bit of research. Using a Pavlovian conditioning procedure, components of the aggressive display of males can be elicited by a previously neutral stimulus that is paired with 15-s presentations of a mirror image of a *Betta*. Punishing the aggressive display with response-dependent electric shock can suppress the aggressive display relative to its occurrence in either the absence of shock or response-independent shocks occurring at the same frequency as the response-dependent ones (Adler and Hogan 1963).

The reactivity of *Bettas* to live and visual images of conspecifics has been mostly widely investigated in the psychology of learning and motivation by using them as reinforcers for some other, operant, response. This latter response produces either a conspecific, usually without physical access to the latter, or a visual image of it. Thompson (1963) conducted a paradigm-establishing experiment in which male *Bettas* learned to swim through a small "O" ring when the consequence was access to a mobile model of a male *Betta* with its fins erect and gill covers extended. In subsequent research involving visual reinforcement with male *Bettas*, the reinforcer for the operant response has included the range of visual stimuli noted above that release the aggressive display. The most frequently used visual image is a mirror image of the fish. There are few direct comparisons of the relative efficacy of these different types of visual reinforcers.

Responses of *Bettas* maintained by visual reinforcement also are a function of several parameters of the visual reinforcer. Thompson and Sturm (1965) reported an interaction between the color of the fish and that of the model as a reinforcer, with dissimilarly colored models maintaining more responding than similarly colored ones. Movement also may affect the quality of the reinforcer, although stationary models also release the aggressive display. Fifteen-second durations of visual access to the image maintained more responding than shorter ones (Wirth et al. 2003). Virtually all of the research on visual-image reinforcement with *Bettas* has been conducted with

males; however, similar operant responses of female *Bettas* also develop and maintain when those responses produce mirror images of themselves (Elcoro et al. 2008).

In most experiments involving visual reinforcement of *Betta* operant responses, each such response produces access to the visual stimulus, that is, a fixed-ratio 1, or continuous, reinforcement schedule has been used. Sustained responding under fixed-ratio schedules of up to a six-response requirement for reinforcement has been reported. Compared to behavior under similar schedules where responding is maintained by food reinforcement, however, response rates do not increase with increasing response requirements (Hogan et al. 1970). In general, intermittent reinforcement maintains relatively low response rates, perhaps in part because the response usually measured is that of swimming to either a particular location or through some barrier such as an “O” ring. Responding previously maintained by an FR 1 schedule was eliminated when the absence of that operant response (swimming to a designated location) for up to 600 s was required to produce brief visual access to a film image of a *Betta* in aggressive display (a differential-reinforcement-of-other-behavior schedule; Turnbough and Lloyd 1973). Because response rates maintained by visual reinforcement are quite low compared to those of more commonly used laboratory species for research on learning, such as rats or pigeons, fixed- or variable-interval schedules of reinforcement often end up being functionally continuous reinforcement schedules because the time between successive responses often exceeds the programmed interreinforcer interval specified by the schedule. Eliminating the visual reinforcer or delivering it independently of responding reduces response rates relative to those maintained when it is response-dependent. Extinguishing responding previously maintained by a visual reinforcer also can result in the resurgence of a previously, but not currently, reinforced response (da Silva et al. 2014).

Operant responses of *Bettas* also can be brought under stimulus control by reinforcing those responses, with either access to visual images or food, reinforcement, in the presence of

one stimulus and not reinforcing that same response in the presence of an alternative stimulus. In what is perhaps the first learning experiment conducted with *Bettas*, Benuic (1932) reported establishing a discrimination between two colors by reinforcing with food approaching one of the stimuli but not the other. The type of stimuli used as the basis for the discrimination also may be important. The present author had little success in establishing an operant discrimination between the presence and absence of mirror-image reinforcement based on either the presence or absence of a change in the color of an incandescent light, but a discrimination was established and maintained when the presence or absence of air bubbles was used as the basis for the discrimination (Wirth et al. 2003).

As a laboratory species for experimental studies of learning, *Bettas* are easy to obtain and maintain, and they typically remain healthy for the duration of an experiment. They also are relatively easy to breed, offering the potential of an inexpensive, replenishing supply of subjects. Their popularity with hobbyists and the material reviewed in this article illustrate that there is sufficient information about their maintenance and general behavior patterns to inform even the most *Betta*-naïve of investigators. To this point, *Bettas* have been a niche experimental subject, used primarily to investigate the reinforcing properties of its unique responses to visual images of itself or other *Bettas*. The *Betta* seems a poor substitute for more common experimental animals such as rats or pigeons for the study of general learning processes because of the, at least presently, not-well-understood limits of its responsiveness to intermittent reinforcement and a lack of data on the sensory systems that underlie its susceptibility to the stimulus control of its behavior. The reproductive and aggressive behavior patterns of *Bettas*, however, have engendered considerable interest and behavioral research.

## Synonyms

[Plane symmetry](#); [Reflection symmetry](#)

## Definition

Bilateral symmetry can be defined as the body plan of those animals, which can be divided into

two equivalent right and left halves along the vertical plane passing through their midsagittal axis.

## Introduction

Body symmetry can be defined as the morphological resemblance of parts in distinct regions and orientations of the body. Because of symmetry, the animals can be broadly divided into bilaterally symmetrical, radially symmetrical, and asymmetrical animals. Animals that can be divided into two equal right and left halves, if they are split in the perpendicular plane passing through their midsagittal body axis, e.g., flatworms, earthworms, humans, etc., are known as bilaterally symmetrical. Organisms that can be divided into two equivalent halves if they are cut through any of the radial planes are described as radially symmetrical, e.g., jellyfish, corals, and sea anemones. Animals that cannot be divided into two identical halves through any plane are described as asymmetrical animals, e.g., sponges, adult snails, etc. (McMurrich 1896). However, precise spherical symmetry is not found in the animal body plans. Interestingly, symmetry type can be either broken or altered from one body type to another during an organism's lifespan (Moubayidin and Ostergaard 2015).

## Bilateral Symmetry

Since bilateral symmetry plane divides an individual into mirror-image halves, this symmetry is also known as plane or reflection symmetry. But, in this case, internal organs are not necessary to be symmetrical. Most of the animals are bilaterally symmetrical with respect to anterior-posterior (AP) and dorsal-ventral (DV) axes, including insects, birds, reptiles, and humans (Fig. 1). These AP and DV axes are formed during early embryogenesis and provide a 3-D coordinate system that gives vital spatial cues for growing cells, tissues, organs, and appendages. The anterior or dorsal end of these animals is characterized by a presence of sensory organs, like visual and the olfactory system (Genikhovich and Technau 2017).

**Bilateral Symmetry, Fig. 1** Bilateral symmetry in the human body along the axis of symmetry

## Advantages of Bilateral Symmetrical Body

Bilaterally symmetrical animals have greater mobility as they tend to move toward a frontal end, which finally led to the localization of their sensory organs in the anterior end or head (through a process defined as cephalization) (Finnerty 2005). This also makes the brain or central nervous system to identify various orientations and positions, thus creating visual perception easier. Moreover, these animals have a more streamlined body shape, which helps in the economical expenditure of energy during movements on land, air, and water. The presence of a similar organ or portion of the body on another side also provides a backup system for critical functions.

## Phylum in Animal Kingdom Showing Bilateral Symmetry

Phyla Platyhelminthes, Aschelminthes or Nematelminthes, Annelida, Arthropoda, Mollusca (except

adult snail), Echinodermata (except adult forms), Hemichordata, and Chordata are the different phyla in animal kingdom showing a good example of bilateral symmetry.

## Bill McGrew

Susana Carvalho and Paco Bertolani  
Primate Models for Behavioural Evolution Lab,  
School of Anthropology and Museum  
Ethnography, University of Oxford, Oxford, UK

## Introduction

William Clement McGrew, born in 1944, is a Scottish-American primatologist and anthropologist, one of the world's foremost experts on chimpanzee behavior and ecology. His scientific productivity is massive, an insatiable writer of more than 450 scientific publications, as articles, books, book chapters, reviews, and commentaries which altogether have been cited more than 13,000 times. These publications cover 15 primate species on a wide range of topics, making an enormous contribution to the development of primatology over the last 50 years.

## Academic Studies and Career

McGrew's academic career started in 1965 with a BSc in Zoology at the University of Oklahoma, USA. In 1970 he was awarded his first doctorate, DPhil in Psychology at the University of Oxford,

UK. In 1990 he obtained another PhD in Social Anthropology at the University of Stirling, UK. In 2009 he was awarded a third PhD in Biological Anthropology by incorporation, from the University of Cambridge, UK.

From 1973, and for almost 20 years, McGrew was first a lecturer, then senior lecturer, and reader in psychology at the University of Stirling, UK. From 1993 to 2005, he was on the other side of the Atlantic, as a full professor in the Departments of Anthropology and Zoology at Miami University, Ohio, USA. In 2005, he returned to the UK, as a lecturer in biological anthropology and soon after became professor of evolutionary primatology at the University of Cambridge, UK. He retired in 2011, becoming emeritus professor at Cambridge and honorary professor at the University of St. Andrews, UK, where he has been based since 2017. During his career, he held visiting appointments at the University of California-Berkeley, University of New Mexico, University of North Carolina-Charlotte, Tulane University, and Earlham College in the USA, and at other academic institutions in Hungary, France, and Germany. McGrew is a fellow of The Royal Society of Edinburgh, Scotland, of the American Association for the Advancement of Science, and of the McDonald Institute for Archaeological Research, Cambridge. He has received the Howells Prize (USA), the Prix Delwart (Belgium), and the Osman Hill Medal (UK).

## Research

The initial subjects of McGrew's first research were young children; his PhD thesis in psychology, entitled *An Ethological Study of Social Behaviour in Preschool Children*, was published as a book (McGrew 1972) and several articles. But in 1972, his research shifted from human primates to nonhuman primates, from children to chimpanzees (McGrew and Tutin 1973). His first ape mentors were captive chimpanzees at the Delta Primate Research Center, in Louisiana, USA, observed during his postdoctoral training (Stanford University, USA). Then, they were the

wild chimpanzees of Gombe Stream National Park, Tanzania, where he was a research associate, when Jane Goodall's famous project was just entering its second decade.

While at Stirling, besides teaching and supervising graduate students, he established a field site in Niokolo-Koba National Park, Senegal. Together with Pamela Baldwin and Caroline Tutin, McGrew was a pioneer in the observation of savannah chimpanzees in the hot, dry, and open habitat of Mt. Assirik. For 4 years in the late 1970s, McGrew made ecological and behavioral observations on the Assirik chimpanzees. Despite these apes being minimally habituated to humans, not allowing observation of their behavior at close range, the naturalistic eyes of McGrew and his team revealed behaviors for comparison with projects of Gombe and Mahale in Tanzania, where the apes were better habituated to human observers. In the following years, McGrew and colleagues published a stream of 42 articles on the Assirik chimpanzees, including highly cited papers that became points of reference in the literature on savannah chimpanzees (e.g., McGrew et al. 1981; Baldwin et al. 1982; Tutin et al. 1983).

Elementary technology has always been central to McGrew's research; one of his first publications on great apes was on captive chimpanzees using tools for dental care (McGrew and Tutin 1973), shortly followed by a detailed description of wild chimpanzees using tools to feed upon driver ants (McGrew 1974). His interest in chimpanzee technology and material culture and their implications for human evolution consolidated in the following years at Stirling. This was the topic of his second PhD, published as a highly-cited book in 1992: *Chimpanzee Material Culture: Implications for Human Evolution* (McGrew 1992). It explores tool use and tool making, diet and food-processing, sex differences, and social customs in the chimpanzee species. It was the first systematic review of the material culture of a nonhuman species and proved to be provocative for scholars in the human sciences. This book, plus two other edited volumes (Wrangham et al. 1994; McGrew et al. 1996), were inspirational to younger generations

of primatologists, stimulating their research and that of scholars of other disciplines.

Unlike most other great ape researchers, such as Jane Goodall, Richard Wrangham, Toshisada Nishida, McGrew was not linked to a single population at a specific field site but instead visited and worked at nine study sites, spanning five African countries. He acquired a wide perspective on the chimpanzee species and a special sensibility for noticing behavioral differences across populations. He hypothesized that a particular grooming posture, the grooming handclasp, seen in some communities of wild chimpanzees, but not in others, may exemplify a social custom in a nonhuman species (McGrew and Tutin 1978). McGrew anticipated the cross-disciplinary debate of the following years on the existence of culture in chimpanzees, in other nonhuman primates, and in non-primate species. He took an important role in the debate in numerous publications (Whiten et al. 1999; McGrew 2004) and in organizing conferences and symposia.

With a remarkable scientific curiosity, excellent communication skills, and a multidisciplinary approach that emerged early in his research, McGrew collaborated extensively with other primatologists as well as researchers of other disciplines, such as zoology, psychology, biological and social anthropology, and archaeology. In the 1990s, he investigated laterality of manual function (handedness), in a series of studies on chimpanzees and other species, which yielded many publications (e.g., McGrew and Marchant 1997). He established long-lasting collaborations with Japanese primatologists Toshisada Nishida and Tetsuro Matsuzawa, contributing significantly to the interaction of Japanese and Western primatology (Nishida et al. 1992). In 1996, he co-organized the symposium Cebus Meets Pan, convening researchers studying tool use, cognition, and other aspects in one or the other species (Visalberghi and McGrew 1997). With Andrew Whiten, he coordinated the collaborative efforts of wild chimpanzee researchers that led to the characterization of chimpanzee culture (Whiten et al. 1999) and the development of cultural primatology (McGrew 2004). Similarly, in more recent years, he had a key role in

organizing symposia and workshops on primate archaeology (Haslam et al. 2009).

Finally, McGrew is an exceptional mentor, with a rich academic lineage. During his career he supervised the research of 18 PhD students and 6 masters students. He has many academic descendants, including grandchildren and great-grandchildren, making him one of the most influential primatologists on earth. Primatology would be a very different world without McGrew's contribution.

## Binary Fission

Pratiti Roy  
Department of Genetics and Plant Breeding (Plant Biotechnology), Banaras Hindu University,  
Varanasi, Uttar Pradesh, India

Binary fission is a method of cell division where the cell divides into two halves by any

plane of division. The classifications of division on the basis of axis of plane are longitudinal (*Euglena* sp.), transverse (*Paramecium* sp.), oblique (*Ceratium*), or just a simple irregular plane of division (*Amoeba*). Bacteria mainly divide by this simple process and have manifold propagation. The cell doubles in its size duplicates the genetic material and finally splits into two. A number of research laboratories have comprehended the underlying molecular mechanisms for this type of asexual method of reproduction in forming clonal cells. Binary fission is also followed by eukaryotic cell organelles like mitochondria and chloroplast which are believed to share bacterial modified genome as theorized by the bacterial endosymbiotic theory.

## Mechanism

Firstly the DNA duplication occurs aided by the action of proteins and enzymes. Then the DNA is segregated to the extreme poles of the cell so that it remains undamaged during division and each cell receives a complement of genes while preserving high fidelity. The site of cleavage finds the assembly of the division apparatus which is comprised of the FtsZ, a class of novel proteins forming a ringlike structure at the center of the cell with its monomers (Angert 2005). Gradually the new cell wall materials are accumulated following the invagination of the cell envelope, and two copies of identical cells are produced.

Hale and de Boer (Hale et al. 1997) were the first to propound a model of bacterial division in *E. coli*.

In Gram-negative bacteria, binary fission is mediated by a group of periplasmic proteins and 12 essential membrane-associated proteins to form the divisome. The assembly of Fts class of proteins like FtsQ, FtsL, and FtsB, forming the FtsBLQ complex, acts as a coordinator for an array of reactions in the divisome (den Blaauwen and Luirink 2019). Evidences of FtsBLQ to have roles in septal peptidoglycan synthesis have been demonstrated for complete division (Boes et al. 2019; Tsang and Bernhardt 2015).

## Proteins and Their Roles in Binary Fission

### Fts Proteins

The Fts class has a multitude of proteins enabling easy prokaryotic fission, and FtsZ is the most vital and highly conserved group in the family. It plays a role in prokaryotic cytokinesis and has structural and functional similarities to the eukaryotic tubulin that aids in the formation of mitotic spindle in eukaryotic cell division. This class of proteins remains conserved even in cellular organelles (like mitochondria and chloroplast) as well as in members of *Archaea*. FtsZ and tubulin are homologous structures (Angert 2005) and share a common ancestor in the line of evolution. These group of proteins form filaments and rings by energy from guanosine triphosphate (GTP).

The various types of Fts proteins that assemble with the Z ring are FtsA, FtsI, FtsQ, FtsL, and FtsW (Angert 2005).

FtsK in *E. coli* were experimentally found to be important in both initial and latter stages of cytokinesis (Begg et al. 1995).

### Other Proteins

It has been reported in *Bacillus subtilis* that Noc<sup>19</sup> do not allow Z ring to assemble at the middle of a cell until the nucleoid segregates. MinCD and DivIV prevent the assembly of Z ring at the poles, EzrA helps in maintaining stability of FtsZ polymers and allow the assembly of FtsZ ring at particular location and YneA destabilize Z ring formation on detection of DNA damage (Angert 2005).

## Conclusion

Du and Lutkenhaus (2017) had reported that majority of the divisome proteins of *E. coli* have been identified although their assembly and septal formation for division is yet to be studied. FtsW is being identified as a putative PG glycosyl-transferase protein for division in coordination with FtsI (Liu et al. 2016). Various proteins encoded by genes contribute toward the

functionality of cellular division while retaining the exact behavior of the cell. This is the most striking feature of binary fission and aids in complete development of a new cell from an older mother cell. Since binary fission indicates toward the clonal propagation of cell by means of an absolutely asexual means of reproduction, hence lack of variation is witnessed by this process. The daughter cells being exact copies of the parent cells have extremely low levels of genetic variation which hinders their survival rate in adverse environments.

## Biogeography

Marc Dupuis-Désormeaux  
York University, Toronto, ON, Canada

Biogeography is the study of the geographic distribution of flora and fauna and the factors that drive this distribution across space and time. Biogeography is an integrative biological science that uses many tools from physical geography to help analyze the composition of species located in any one area. Factors that affect the composition of plant and animal species at one site are varied and depend upon specific climatic and physical characteristics (local climate, latitude, elevation, isolation), geological factors (from plate tectonics to soil composition), and evolutionary history (colonization, extinction, and speciation). Further, the ability of any given species to adapt to the local conditions will affect both its range and its ability to disperse further on the landscape. Biogeography and landscape ecology are closely

related subjects, the former more concerned with connectivity and movement over the landscape and the latter more focused on the functional aspect of the habitat at varied spatial scales. Landscape ecology concerns itself with the processes (biotic and abiotic) and organisms that preserve proper ecosystem functioning and ecological integrity. Anthropogenic effects leading to fragmentation and loss of connectivity can decouple mobile organisms and processes from their ecosystem role and lead to an impoverished and unstable habitat structure that changes species dynamics and composition.

Much of the early genesis of modern biogeography stems from the works of notable nineteenth-century geologists, explorers, and naturalists. In particular, the works of Alexander Von Humboldt and after him, Alfred Russel Wallace stand out as most influential. Von Humboldt was an explorer and travelled extensively, recording detailed geophysical measurements as well as describing his journeys and the species he encountered with the help of a botanist, Aimé Bonpland. Von Humboldt was a prolific writer and published accounts of his travels, as well as specialized works on astronomy, botany, and zoology. Wallace also was an avid explorer and collector of specimens. His work focused on species distribution across the world by integrating evolution by natural selection (which he co-proposed with Charles Darwin) and geography. By carefully noting geographical features of the many thousands of species he studied, Wallace noticed that places on Earth that shared similar climate and terrain did not necessarily share similar species. In particular, he noticed a clear demarcation of species between the neighboring islands of Java, Sumatra, and New Guinea and how species in Java and Sumatra were more closely related to the Asian continent and that New Guinean species bore a close resemblance to Australian species. He delineated six biogeographical regions on the planet that eventually matched up with continental drift and plate tectonics.

Robert MacArthur and Edward O. Wilson wrote one of the seminal works of biogeography, *The Theory of Island Biogeography* (MacArthur and Wilson 1967). The authors developed a model

to explain species richness on oceanic islands based on a series of extinction and re-colonization experiments conducted off mangrove islands off Florida. Their theory proposed that smaller, more isolated islands contain fewer species and that these species are more prone to extinction. Research on arthropods (Simberloff and Wilson 1969) and birds (Diamond 1973, 1974; Terborgh 1974) supported this theory. Researchers found that immigration and emigration relate to the distance to the mainland source population (colonists) and extinction rates correlate inversely to island size (i.e., the larger the island, the smaller the probability of extinction due to stochastic events). Eventually, the island populations/communities stabilize at equilibrium. Biologists drew parallels between real islands and isolated ecosystems on continental mainland. However, when biologists applied the island biogeography models to empirically test virtual “islands” such as land-locked reserves and isolated mountaintops, they found that extinction (and emigration) rates surpassed colonization rates and that no equilibrium was reached (Brown 1971). Others found a correlation between extant diversity of species and the quality of the habitat, i.e., both the gross area and heterogeneity of the landscape (Newmark 1986). Early applications of island biogeography also drew criticism as researchers found that under heterogeneous habitat conditions, smaller refuges could harbor a larger total number of species (Blake and Karr 1986; Quinn and Harrison 1988; Simberloff and Abele 1976) and that subdivided populations were more likely to persist (Quinn and Hastings 1987). The key finding was that heterogeneous landscapes provided more opportunity for species diversity. With the development of phylogenetics combined with known dispersal drivers, predicting patterns of species dispersal has become more rigorous and successful and has led to developments in the field of conservation biology.

Using satellite imagery to map changes in the habitat as well as the effects of human encroachment, modern biogeography focuses on how environmental and anthropogenic factors can influence the distribution and persistence of specific species of study. Modern biogeography can

play an important role in detecting likely changes to the distribution patterns of species, help identify movement corridors, and predict long-term persistence of species in the face of climate change and other sources of landscape-wide threats.

## Definition

Bioinformatics is a field of biological data storage, retrieval, management, and analysis by applying techniques from computational sciences, mathematics, and statistics.

## Introduction

Biological sciences have been undergoing a paradigm shift due to tremendous progress in experimental methods over time. These methods are generating biological data at an unprecedented rate at genomic and organismal levels. It includes DNA and protein sequence data and their three-dimensional structures, taxonomic data-aiming to catalog every living species on the earth, metabolic reaction data which charts metabolic pathways in an organism to understand physiology, molecular interaction data which reveals how cellular components interact to drive biological processes, gene expression data which provides snapshots of RNA species present at a particular

time point in a cell, and biomedical text data which provides a rich source of biological information scattered in literature. These data are diverse in nature and analysis is generally challenging due to inherent complexity of biological systems. Data analyses require skills not only from biological sciences but also from computational sciences, statistics, and mathematics. The field of bioinformatics bridges this knowledge gap by dealing with biological data storage, retrieval, management, and analysis by using computational tools and techniques in statistics and mathematics. The field of bioinformatics is vast, evolving over time and difficult to describe in a single chapter. This chapter provides a glimpse of the bioinformatics tools that are useful for experimental biologists and covers selected important developments in the field.

## Biological Databases

Biological data is mostly available in relational databases with user-friendly interfaces accessible online. With few exceptions, biological databases are publicly available for research. Many prediction and inference web tools were developed in parallel to biological databases for in-silico biological discoveries. The available web tools and databases are thousands in numbers and ever increasing. In 1965, Margaret Dayhoff collected 65 protein sequences that were sequenced by the time and reported them in a book titled *Atlas of Protein Sequence and Structure*. It subsequently led to the foundation of bioinformatics and the first online database, the Protein Information Resource (PIR). Dayhoff was also first one to compare sequences using computer program (Eck and Dayhoff 1966). Meanwhile, efforts made to develop the GenBank, a nucleic acid database which was eventually released in 1982. Since then, GenBank, as a part of the National Center for Biotechnological Information (NCBI), has become the first stopover for research in almost all biological fields and growing at an exponential rate, containing millions of sequences including thousands of completely sequenced genomes (Wheeler et al. 2000). GenBank

provides up-to-date information about nucleic acid sequences wherein each entry is further hyperlinked to other related resources providing fine-grained information such as protein sequence, taxonomy, metabolic pathway, etc. The universal protein knowledgebase (UniProt) is a modern database which contains as of July 2017, 555,100 manually annotated and reviewed protein sequence records with information extracted from literature about molecular functional aspects, and 88 million sequences with electronic annotation, i.e., translated from nucleic acid sequences from GenBank-like databases (SIB Members 2016). Researchers are continuously analyzing sequences in these databases and others to gain biological insights and to create several specialized databases.

The list of biological databases is never ending but the most important databases are: Pfam, a database of protein families and domains related information; ProSite and InterPro are databases of protein functional sites or patterns found specific to a particular protein family which include active sites, binding sites, unique patterns, etc.; Gene Ontology (GO), a database of structured and hierarchical classification of genes into three functional categories that are biological process, cellular component, and molecular function, each further refined up to seven levels from the broader to finer functional subclasses; the Kyoto Encyclopedia of Genes and Genomes (KEGG), a database of metabolic enzymes, reactions, and pathways; DNA Binding Domain (DBD), a database of predicted transcription factors in completely sequenced genomes; JASPAR, a database of transcription factor binding sites; Online Mendelian Inheritance in Man (OMIM) database provides quality information on human genetic disease related genes; the Ensembl database provides user-friendly programmatic access to annotation and sequences of eukaryotic genomes; PubMed, a biomedical literature database containing millions of research publications; the Protein Data Bank (PDB) database contains 3D structures of macromolecules and associated information, whereas the superfamily database contains PDB structure-based protein family and domain classification system. Searching these

databases is easy and can be done by using a sequence, gene or protein names or keywords associated with them. More complex Boolean queries are also possible through advanced search options for filtering relevant information. Table 1 enlists these and few other important databases with weblinks for access. Readers are further encouraged to explore the resources available at NCBI, EBI, ExPASy, and the UCSC genome browser, which have strong user support (Table 1).

## Overview on Sequence Homology-Based Protein Function Prediction

For many centuries, the homology term has been used to describe the common ancestry between a pair of biological entities based on notable common features. In the early 1960s, Emile Zuckerkandl and Linus Pauling analyzed sequences available at that time and observed that the homologous sequences share a high degree of similarity and small number of differences. They speculated that the comparison of homologous sequences from various organisms can be used

to understand the process and rate of evolutionary changes at molecular level. This observation was key to the development of a series of computational methods to align, compare, and analyze sequences (Altschul et al. 1997). Given a query sequence, Basic Local Alignment Search Tool (BLAST) and phmmer (part of hmmer package) web/stand-alone tools search it in sequence databases like GenBank, UniProt, or PDB. Generally, if these tools identify database sequences (called hits), with more than 60% identity with the query sequence and an e-value (the measure of obtaining hits with as high identity by chance in the database) below  $1e-4$ , then it is very likely that identified the query sequence's homologues. If there are homologues with known functions, these may be putative functions for the query sequence. The BLAST and phmmer are pair-wise alignment tools and can search databases of millions of sequences within a minute. Hits with 30–60% identity to the query sequence and a significant e-value can be used to construct multiple sequence alignments using several available tools. Clustal family tools are the most used ones. Due to mutations, insertions, and deletions, sequences diverge during evolution – however,

functionally and structurally important regions are conserved and can be revealed in multiple sequence alignment for functional inferences.

Distantly related homologues will often not be identified by above-mentioned tools, typically if they share less than 30% of their amino acid sequence with the query sequence. In order to identify them, more sensitive sequence-profile based tools such as Position-Specific-Iterative BLAST (PSI-BLAST) or Jackhmmer (hmmer package) can be used. In the first round of database search, these tools identify definite homologues of the query sequence. Using resulting pair-wise alignments of query and hits, at each position of the query sequence, the occurrence of each of the 20 amino acids will be computed. The resulting matrix is called profile and captures the information from several hits about the amino acid changes that evidently happened at each position of the query sequence. The tools then search the profile instead of the single sequence in the next rounds of database searches to find remote homologues. It has to be noted that a

large fraction of eukaryotic proteins harbors more than one domain, each with its own homologues. A domain is a region of a protein sequence which evolves independently, performs a specific function, and adopts a characteristic three-dimensional structure. PSI-BLAST or Jackhmmer often fail to detect true homologues for multi-domain protein sequences. It is recommended to use specialized tools to identify these domains. Pfam and Superfamily databases provide Hidden Markov Models (HMM) of all known sequence or structure-based domains, constructed using profiles of homologous sequences of each domain. Each HMM contains evolutionary model of a individual protein domain. A protein sequence can be submitted to these databases, to identify its domain architecture using programs from hmmer package and HMM library of all domains (Finn et al. 2015).

Essentially, if above-mentioned tools identify a single well-characterized homologue for a protein of interest, then user is already close to deduce its function at molecular level (Table 2). When all

sequence-based tools fail to identify homologues, Phyre2 or I-Tasser-like three-dimensional structure prediction tools may be used, because structures are more conserved than sequences. These tools also include putative ligand binding sites in their structure prediction results. These approaches can only infer functions of proteins that are homologues to already well-characterized proteins. The fact that biologist determines protein functions in controlled laboratory setup where most protein coding genes do not express.

## Overview on Nonhomology-Based Protein Function Prediction

On an average, 40% proteins from sequenced genomes do not show sequence similarity with well-characterized proteins. Their functions are crucial to understand the complete biology of organisms. The post-genomic researchers developed several methods to provide broad functional roles to these proteins. Proteins involved in the same biological processes are often under the same functional constraints and tend to co-occur in genomes where that function is required. Phylogenetic profiling method detects such co-evolving protein pairs. The function can be inferred for uncharacterized protein based on the functions of characterized proteins coevolving with it. MirrorTree method also captures coevolution of protein pairs but at amino acid level changes. The idea is based on the need of physical interaction between cooperating proteins to drive function. Hence, mutations at the interface in one protein are likely to be compensated by mutations in the other. This information can be computed from multiple sequence alignments of two protein families.

Chromosomal proximity of genes often indicates coregulation and hence the requirement to express them at the same time point in the cell. The protein products of such coregulated genes often physically interact with each other and contribute to protein complexes. Coregulated proteins can be detected by the intergenic distance between the genes encoding them. Coexpression of genes is a hallmark of their coregulation, which can be computed from hundreds of gene expression

datasets for various organisms publicly available at Gene Expression Omnibus (Table 2).

Generally, these methods detect interacting partners of proteins encoded in the same genome. The function of an uncharacterized protein is often deduced from the functions of its interacting partners; hence, these methods are known to employ the guilt-by-association principle or genomic context (Snider et al. 2015). These methods do not provide functional information at molecular level but often deliver clues to the biological process or pathway in which the protein of interest may act. String web server implements several such methods and can be searched using sequence or gene name to identify interactions (Table 2).

## Machine-Learning Classifiers in Bioinformatics

Bioinformaticians have spent significant effort in classifying millions of publicly available sequences into various categories. For instance, databases like Pfam and Superfamily contain HMM for almost all known proteins or domains. Unclassified protein sequences can be classified into known families based on HMMs using hmmer-like tools. Given a positive and negative training data set, machine-learning techniques build classifiers based on certain features derived from training dataset. The classifier can be defined as a mathematical or statistical coding of the features, which distinguish instances of the positive or negative class and classify also new instances. Machine-learning classifiers have been developed for the classification of almost all biological entities. The list includes the prediction of genes in completely sequenced genomes using Genmarks, Genscan, Fgenesh, etc.; to the prediction of promoter sequences and transcription factor binding sites using Jasper; the prediction of subcellular localization of proteins using Phobius, SignalP, PSORT, TargetP, etc; to the prediction of gene expression using codon (genetic code) usage and prediction of protein–protein interactions using genomic context; secondary and tertiary structures of proteins using PSI-Pred, Phyre2, I-Tasser, and several others. This list of machine

learning classifiers developed in bioinformatics is never ending (few in Table 2) and encompasses almost all possible applications (Libbrecht and Noble 2015).

## Next-Generation Sequencing Data Analysis

Next generation sequencing (NGS) technology caused a paradigm shift in experimental biology. Sequencing the genome is no longer an expensive and time-consuming affair. NGS technology is coming up with wide applications and can be used to sequence complete genomes, RNAs (along with gene expression profiling), transcription factor binding sites, nucleosomes bound DNA regions, and several other (Lee et al. 2012). NGS generates data in the form of millions of short segments of DNA regions called reads. These reads are then further refined to prepare the data for analysis. The choice of tools depends on the length of the generated reads. Every NGS analysis starts with the assembly of the processed reads to recover the complete DNA regions of interest (Martin and Wang 2011). This step is easy when a reference genome sequence is available for the organism for which the NGS data was generated. Reads can be mapped to the genome and assembled. The assembled reads then can be analyzed further depending on the type and aims of NGS analysis. Galaxy is the best online tool for NGS data analysis from preprocessing of the reads to inferring biological meaning.

NGS data analysis is already making an impact on all fields of life science, from basic biology to translational research. The Encode project used NGS technology to decipher gene expression in several human tissues, refine gene boundaries, promoter usage, isoform usage, genome-wide mapping transcription factor binding sites, and mapped epigenetic modifications across genomes in several cell tissues and cell lines. Many metagenomics (sequencing microbial community without culturing) projects have been completed providing snapshots of microbial diversity in several sites in oceans and also in human body (Oulas et al. 2015).

<sup>2</sup>Animal Behavior Core, Department of Comparative Medicine, The University of Nebraska Medical Center, Omaha, NE, USA

## Synonyms

Biological cycle; Biorhythm; Body clock; Circadian rhythm; Circannual cycle

## Definition

Internal mechanism responsible for the behavioral changes that occur through yearly, seasonal, or daily cycles.

## Introduction

Biological clocks are universal in that they are found in virtually all living organisms. These clocks are constituted of molecules that play important physiological roles in activities that are integral to the existence of living organisms. Such activities include vital bodily functions such as sleep-wake cycles, daily eating habits, and the regulation of body temperature. Not only do biological clocks contribute to daily changes such as circadian rhythms, but they also influence an individual through a variety of temporal scales, such as seasonal and lifetime changes. These circannual clocks are often associated with reproduction. The animal kingdom has a variety of adaptations that are governed by these biological clocks.

## Daily Cycles: Circadian Rhythms

The circadian rhythm is a type of biological clock that operates throughout a daily cycle.

Circadian rhythms impact both mental and behavioral changes that are associated with diurnal periods. These cycles are controlled and regulated by a part of the brain within the central nervous system that triggers different activities as a result of exposure to extrinsic signals. These periods occur even when it is not exposed to constant environmental cues, thereby maintaining the bodily functions necessary to occur for survival.

Circadian rhythms within the animal kingdom occur due to exposure to a variety of external cues. A common external cue such as a light stimulus can instigate the circadian rhythm. Subsequent variations in interval and extent of light exposure can in turn impact the latency and duration of daily sleep cycles. Other than light, there is a diverse range of external cues that impact the circadian rhythms within the animal kingdom. For example, some species use tidal rhythms to determine when to forage in the sand while other species, such as marine worms, rely on the rise and fall of the moon to decide when to spawn (Martin and Swiderski 2001). Aside from tidal and lunar clocks, some animals, such as honeybees, have shifts in their respective circadian rhythm dependent on their social roles. Forager honeybees tend to have more regular circadian cycles, while nurse bees undergo shifts in their circadian rhythms to adjust to caring for their larvae (Eban-Rothschild and Bloch 2012). Furthermore, not all biological clocks within the animal kingdom span a 24 h period; in fact, some animals like the Somalian cave fish experience a much longer cycle, reflecting the slower environmental changes that occur within the darker caves (Beale et al. 2016). On the other hand, animals, such as the voles, undergo shorter cycles that last for about 2–3 h (Gerkema et al. 1993).

Biological clocks are not only important in producing these circadian rhythms but are critical in their regulation as well. Animals rely on the successful regulation of these internal cycles in order to sustain day-to-day functionality and survival. The variations in circadian rhythms, spanning differences in duration, trigger stimuli and, more, showcase the diverse ways by which animals in the animal kingdom respond and adapt to daily changes.

## Seasonal Cycles: Migration and Dormancy

Animals change their behavior and physiology in daily or annual cycles. Many aquatic species perform diel (daily) vertical migrations, where they move up in the water column to forage at night and move down during the day. Other organisms prepare to move to different locations at different times of the year. Large marine mammals, such as humpback whales, migrate to high latitudes to feed on krill and move to the tropics to breed and rear young (Baker et al. 1990). Birds experience *Zugunruhe* which is a change in behavior that includes increased activity around dusk and changes in their sleep cycles during migration periods (Rattenborg et al. 2004).

Another annual adaptation is seasonal dormancy, which is characterized by inactivity and decreased metabolism. Aestivation is seasonal dormancy in summer months and hibernation occurs in winter. Many invertebrates and ectothermic vertebrates have an aestivation cycle to conserve energy. Endotherms, such as mammals, are the most likely group to experience hibernation. Bears spend winter months in hibernation, spending long periods of time sleeping to reserve energy during the time of year when food is least plentiful. Female bears put their energy into gestation during hibernation, giving birth to their young during hibernation or shortly afterward. Hibernation can affect circadian cycles as well. In European hamsters, the circadian rhythm loses its 24 h oscillation during hibernation periods (Revel et al. 2007).

## Age/Fertility

As animals age, they experience a variety of changes in their behavior and form. Most notably, organisms experience a shift from non-reproductive to fertile life stages. Species such as butterflies and amphibians experience metamorphosis, altering their body shape to become reproductive. Other species, such as mammals, go

through a physiological process that allows them to reach sexual maturity with little or no change in form. Many species engage in sexual behaviors, such as copulation or courting. Mating begins once an animal reaches reproductive age. In female cockroaches, it has been shown that reproductive aging caused by delayed mating resulted in reduced choosiness of mates (Moore and Moore 2001). Few species have a post-reproductive life stage. One such species is the killer whale, where females that reach post-reproductive age provide leadership to their family groups (Brent et al. 2015).

## Conclusion

Biological clocks play an important role in animal behavior. Changes in behavior are often associated with reproductive success. Disruptions in these daily and temporal cycles could lead to complications impacting survival and overall health. Although biological clocks are an internal and self-sustained mechanism, they are often regulated due to exposure of external cues. From an evolutionary perspective, adapting to external stimuli that may impact biological cues could prove to be highly advantageous especially in the current climate facing constant environmental changes.

## Biological Preparedness

Aimee S. Dunlap  
Department of Biology, University of  
Missouri – Saint Louis, Saint Louis, MO, USA

### Definition

Biological preparedness is a broad explanation for why some associations are learned more easily than others, invoking the evolutionary history of the animal.

### Introduction

Animals appear to learn about some stimuli in the world better than others, and a number of studies have shown that some sets of stimuli seem to be more easily associated than others. Some explanations exist for why this might occur, including ideas of belongingness and preparedness. Biological preparedness was first introduced as a term by Martin Seligman in his seminal paper “On the generality of the laws of learning”

(Seligman 1970). As with any trait, learning and behavior in any species are the result of evolutionary processes. Broadly speaking, learning enables an animal to use past experience to inform future behavior. Learning allows an individual to better track a changing environment, and this plasticity forms the foundation of flexible behavior. While the neurological mechanisms underlying learning are highly evolutionarily conserved and shared among animals, we see large differences in what animals can learn about, and what associations animals can make more easily than others. Seligman explained these differences as a product of the biology of the animal and of its evolutionary history: An individual of a species is born more prepared to learn about some associations than others because those associations were more useful for the ancestors of that individual. This makes intuitive sense when one considers that animals are bombarded with stimuli and potential associations from birth. If all stimuli were held equal, the extended trial and error learning required to differentiate among the potential stimuli and outcomes would likely result in incredibly high mortality in young animals. And, indeed, there are many examples of spectacularly fast learning in the natural world. For instance, butterflies can learn associations of where to lay eggs after single experiences (e.g., Snell-Rood and Steck 2015), and cues of predation or danger are very quickly learned from conspecifics (e.g., Cook and Mineka 1990; Ferrari et al. 2012).

### **History: From Behaviorism to Preparedness, Constraints, and Adaptive Specializations**

Early in his writings on learning, Thorndike (1911) speculated that the neural connections present within an animal may constrain what it can learn. Twenty years later, Thorndike (1932) wrote that the elements within learning that “belonged” together are more easily associated than elements lacking such a relationship. He referred to this as belongingness. Thus, how well something is learned is not determined by contiguity alone. In Thorndike’s view, an animal that is thirsty would

more readily learn an association that contained an effect of water because such an effect belongs to the needs of the organism. An effect that “belonged” less would not elicit as strong a reaction. In this way, animals would show better learning to more appropriate pairings of stimuli and effects than to less appropriate pairings. Thorndike’s view of belongingness emphasizes the particular states of the individual, but how should differences in species be interpreted?

The approach of behaviorism saw the testing of many animal subjects under tightly controlled and replicated conditions. It was generally hypothesized that learning was governed by a series of common laws, and detailed study of model species could then apply broadly across all animals. During the 1960’s and beyond, a larger variety of species and tasks were being used in studies of learning. This led to an increasing number of potential exceptions to the generally regarded laws of learning, including two frequently cited studies which provide good examples of selectively learned information. In a study with dogs, Dobrzecka et al. (1966) compared qualitative and directional auditory cues in differentiation learning instrumental task. In a right leg-left leg differentiation task, dogs almost exclusively learned using the directional cues with the qualitative cues not being learned even after more than 1000 trials. Complicating the conclusions further, they found that in a go-no go task, dogs acted with the quality of the cue 80% of the time, but acted with the direction of the cue 20% of the time. In this study, not only are certain stimuli and responses learned better than others, but the effect is task-specific. During the same year, Garcia and Koelling (1966) showed that rats select the cues used as stimuli dependent on the nature of the reinforcement. Rats were given water that differed in taste and in audiovisual characteristics: “bright-noisy” water and “tasty” water. Rats drinking these types of water were later made ill using X-rays and lithium chloride. Garcia and Koelling found that avoidance reactions developed based on the taste cues but not the audiovisual cues. However, when paired with shocks, rats learned the audiovisual cues better than the taste cues. Again, different cue types are being learned in

different tasks. Both papers were thought to pose challenges to the assumed generalities of the laws of learning and sparked a debate on the possibilities and potential types of biological constraints on the general process of learning (e.g., Seligman 1970; Shettleworth 1972; Logue 1979; Damianopoulos 1989).

A major idea proposed to explain the phenomena found by Dobrzecka, Garcia, and others was that of biological preparedness. Seligman (1970) argued that animals are born biologically prepared to learn certain associations, meaning that there is no equivalence of associability across all learning and all animals. Animals can also be contraprepared to learn. Contraprepared learning describes the difficulties in conditioning animals with certain tasks, such as with having a cat lick itself to escape a box. Seligman argued that animals show a continuum of preparedness, where learning about different events could be prepared, unprepared, or contraprepared. Examples from classical and instrumental conditioning, and discrimination and avoidance learning were discussed, with preparedness argued to be relevant to each of these types of learning. Whether prepared learning is qualitatively different from general learning was left an open question by Seligman due to the lack of experiments at the time. Additional questions proposed by Seligman were whether prepared learning covaried with additional cognitive or physiological mechanisms.

Shettleworth (1972) proposed a more general idea of biological constraints on learning in a detailed review of such constraints in every step of the learning process. Biological constraints on learning are essentially species-specific reactions to certain learning situations which are overlaid upon the factors operating in traditional learning theory. In other words, associative learning is the same across all species and situations with the exception of these biological constraints. She criticized Seligman's notion of preparedness as being focused on associative learning as the cause for observed differences in associative learning that also could be due to nonassociative processes. Shettleworth also discussed the importance of learning in the wild and described how

psychological ideas of learning could be applied to behaviors such as movement patterns and orientation. Shettleworth suggested that in studying learning, the behavior of animals in the lab should be related back to their behavior in the wild. Robert Bolles wrote about specific examples of this, proposing that some responses are likely constrained by Species-Specific Defense Reactions (e.g., Bolles 1970). He used example of flight reactions in rats when presented with aversive stimuli such as shocks.

In the following years, ideas of biological constraints became more specific, and were spoken of as adaptive specializations (e.g., Rozin and Kalat 1971; Shettleworth 1994). The notion of adaptive specializations specifically addresses the covarying cognitive and physiological mechanisms mentioned by Seligman. The use of the term adaptive specializations implies that such differences are the result of natural selection. Within the specific context of memory, Sherry and Schacter (1987) described the evolution of specific memory and learning systems as a result of functional incompatibilities between different tasks. Evolved modules would be well-suited to performing different tasks, such as food storing and retrieval behaviors in birds (e.g., Shettleworth 1990), and these adaptive specializations could then explain examples of preparedness described in learning. The notion of adaptive specializations is not without critics, but certainly every exception to general processes of learning does not require an explanation rooted in adaptive specializations (e.g., Krause 2015). Constraints do exist, and arguments using evolutionary adaptive logic can and should be empirically tested.

### **Prominent Examples of Preparedness: Taste Aversion, Fear, and Phobias**

The biological importance of taste aversion is straightforward to invoke as forming fast associations to enable avoiding potential toxicity in food is undoubtedly adaptive. An indeed, a taste aversion was invoked frequently as an early example of preparedness (e.g., Rozin and Kalat 1971; Logue 1979).

This logic is especially true for generalist foragers such as rats, with a well-described mechanism for social learning of food odors. The textbook example of preparedness is the work by Garcia and Koelling (1966). Among other results, they found that rats quickly formed associations between taste and nausea, but were unable to form associations between light and sound, and nausea. This work was the start of a burgeoning literature on biologically prepared taste aversion. Recent work on prepared learning and taste aversion in an ecological context is looking at how predators learn to avoid aposematically colored and toxic prey. Aposematic coloration, or warning coloration, poses an evolutionary question because the potential prey item is conspicuous to predators and every predator must first learn that association between coloration and toxin (Skelhorn et al. 2016). First, there is prepared learning for bitter tastes and toxicity, resulting from an evolved response to bitterness reliably predicting toxic effects (e.g., Skelhorn and Rowe 2010). Additionally, the conspicuousness of the prey enables an easier detection by the predator, is easier to learn, and less likely to be forgotten (e.g., Alatalo and Mappes 1996; Prudic et al. 2007; Roper and Redstone 1987). Thus, within one ecological paradigm, multiple levels of preparedness can be predicted and observed.

A second area with a deep literature on preparedness with fear and phobias, primarily in humans and other primates, is fear conditioning, which like avoiding toxic food, is easily tied logically to ecological relevance. Animals should more quickly form associations among stimuli that can result in their harm or death. The most famous of these examples is the work of Cook and Mineka (1990), who demonstrated selective associations at play in the observational conditioning of fear in rhesus monkeys. In their study, monkeys selectively associated snakes with fear and did not selectively associate more biologically neutral stimuli, such as flowers, with fear. Additional studies of fear conditioning generally confirmed these results across a range of ecologically relevant and neutral stimuli (e.g., Ohman and Mineka 2001). This type of fear conditioning has also been proposed to be evolutionarily tied to the development of phobias.

Phobias in humans seem to develop around specific objects, animals, or situations and are not equally distributed among other types of stimuli; thus, it is widely thought that phobias may represent a particular case of preparedness (e.g., Seligman 1971; Ohman and Mineka 2001).

## Mechanisms for Preparedness

A specific mechanism proposed for some examples of preparedness is that of selective associations. Selective associations require an interaction between the stimulus and reinforcement that results in faster acquisition of a CR with one CS than with another, but an opposite effect with a different reinforcement (LoLordo 1979). Additionally, the differences in learning must be due to this interaction and not to any differences in any particular properties of the stimulus used, such as its salience or intensity. This quite specific definition requires a series of controls to ensure that the observed differences are indeed due to selective associations, and LoLordo reviews possible methodologies to use for testing for a selective association. A straightforward approach is provided by Linwick et al. (1981), and they emphasized using correctly chosen controls and using a bidirectional design such that excitatory and inhibitory effects upon the dependent measure could be seen, without any floor or ceiling effects that might mask important differences. It is important to note that selective associations are not the only form of preparedness described in animals, as evidenced by the many other mechanisms that can result in prepared or contraprepared learning. Selective nonassociative processes may be adequate to produce the biologically appropriate, or prepared, response to the situation.

Given that natural selection acts upon fitness rather than mechanism, the output of the learning and not the process may be what should be considered from an evolutionary point of view. Seligman predicted that physiological and cognitive aspects would vary along with the continuum of preparedness for learning specific associations in animals. Evolutionary processes can prepare animals to learn some associations more easily

than others through acting on multiple cognitive systems, from perception to motivation to learning and decision making. In a broader biological view of learning, we know that this must be the case. Harkening back to Shettleworth's list of biological constraints, an additional 45 years of work on the neurobiology and sensory biology of cognition have finally enabled a more full conception of mechanisms through which preparedness happens. For instance, there is currently a strong emphasis on the role of sensory bias in the evolution of animal behavior (e.g., Ryan and Cummings 2013; ten Cate and Rowe 2007), and a myriad of ways that such a bias might be accomplished across perceptual systems (Stevens 2013). Once perception of a stimulus is possible, both selective attention and sampling behavior, the tendency to encounter stimuli and the experiences which lead to forming associations can affect what is learned (e.g., Knudsen 2007; Snell-Rood and Steck 2015). Within nonassociative learning, we can predict that biological prepared learning may be enhanced through greater sensitization and more difficult to habituate to. Within classic associative learning, two relevant paradigms address how biological preparedness may enable certain associations to become learned over others. The first is that when multiple stimuli are present as the animal learns, the more salient stimulus can overshadow potential learning of another stimulus. The second is that a prior exposure to a salient stimulus can then block the learning of any future presentations of a different stimulus. Both overshadowing and blocking occur frequently in studies, and are a predicted consequence of preparedness (e.g., LoLordo 1979). Prepared learning should also be resistant to extinction: being persistent in performing a learned response in the absence of the original reinforcement (like a reward or a shock). We can also predict that biologically prepared learning should be forgotten less quickly. Work in both psychology and behavioral ecology predict that more important information should be remembered for a longer period of time; forgetting will be adaptive for certain stimuli and experiences (e.g., Dunlap et al. 2009; Ferrari et al. 2012; Kraemer and Golding 1997).

## Predicting Preparedness

The majority of work to date on preparedness in learning has focused on post hoc explanations of observations or of patterns uncovered in behavioral experiments. There are exceptions to this. For instance, Domjan et al. (2004) hypothesized differences between arbitrary and ecologically relevant stimuli in sexual conditioning contexts. While predictions of preparedness in terms of fear conditioning and phobias have been made, empirical results can be mixed. A primary problem has been the lack of predictive models. The first general theoretical model on how preparedness can evolve focuses on the reliabilities of stimuli that can be learned about (Dunlap and Stephens 2014). Building upon earlier models of the evolution of learning broadly (e.g., Dunlap and Stephens 2009; Stephens 1991), reliability is set as a contingent probability of a given cue accurately predicting an outcome. Because statistical properties of change are both measureable and empirically tractable, this allows for direct tests of when prepared learning will evolve. And, indeed, using the techniques of experimental evolution, it is possible to evolve prepared learning about some modalities of stimuli over others, directly testing this theory; Dunlap and Stephens showed exactly this with fruit flies, evolving flies that learned about color better than odor, and other flies that learned about odor better than color, matching the predictions of the model. By making predictions from reliabilities of stimulus-outcome contingencies, preparedness can also be more directly tested within single lifespans, in addition to across generations.

## Conclusion

Notions of biological preparedness have a long history in the study of animal cognition. Preparedness has most often been invoked to explain quick learning in high-risk situations: predation, harm, potential poisoning. While it is easy to imagine the evolutionary implications of death, biological preparedness can equally apply toward appetitive or sexual stimuli. Although much past work has

focused primarily on the role of selective associations in preparedness, evolution selects on outcomes and not mechanisms and biological preparedness in learning can be accomplished through a number of mechanisms, both associative and nonassociative. The evolution of biological preparedness can be predicted through an analysis of patterns of reliability of relevant stimuli, thus providing a guide for empirical work rather than a reliance on post hoc explanations.

animals to time reproductive activities such that offspring will be born during seasons of food abundance. White-tailed deer mating season takes place in autumn with the resulting fawn being born during the spring months when food supplies are becoming more abundant for these herbivorous animals. Some animals exhibit changes in predation behaviors according to lunar cycles. Nocturnal predators increase activity levels during the full moon (high nocturnal light levels) compared to new moon (low nocturnal light levels) to facilitate predation, while prey species exhibit the opposite behavioral pattern to avoid predation (Nelson 2011). The temporal variation in behaviors, such as mating and predation, presumably reflects temporal variation in the physiological processes governing the behaviors; the relationship between temporal variation in behaviors and physiological processes is the basis of biological rhythms. **Biological rhythms** are recurring events within an organism that take place at generally regular intervals (Kalmus 1935). Biological rhythms are a characteristic shared by many organisms, even single-celled life forms (Takahashi 1991). Biological rhythms work by way of biological clocks to not only govern the timing of activities such as mating, foraging, and sleeping, but they also govern internal physiological processes such as hormone secretion. Understanding how biological clocks receive, evaluate, and integrate environmental information to control physiology is of great importance, because chronic disturbances of circadian rhythmicity have been linked to pathological states.

## Biological Rhythms

Jacqueline Hill Tudor  
Ohio University, Lancaster, OH, USA

### Introduction

Organisms have evolved to time activities, such as feeding, drinking, sleeping, locomotion, and mating, to specific temporal niches. Timing specific activities may confer an evolutionary advantage to organisms. For instance, it is advantageous for

### Biological Rhythms Are Maintained by Biological Clocks

Biological rhythms are composed of several key components, including a period, frequency, amplitude, and phase. The **period** is defined as length of time for one complete cycle of the biological rhythm. The **frequency** of a biological rhythm quantifies the number of biological rhythm cycles per unit time. **Amplitude** refers to the amount of change above or below the average biological function. A **phase** of a biological

rhythm refers to some point in the rhythm to an objective time point during the cycle. For instance, diurnal animals' (active during day) phase of onset of activity corresponds to the onset of light. **Phase-shifts** occur when an animal adjusts to alternative timing of environmental cues. If environmental cues are phase-shifted (e.g., if lights are turned off 6 h later), a laboratory-kept hamster will adjust activity timing to the temporal shift of environmental cues (Nelson 2011). Humans experience a similar phase-shift incident when traveling to different time zones (jet lag). A biological rhythm may overlap with or influence other biological rhythms. For example, human body temperature oscillates around a set point established by the hypothalamus. Studies have shown that when humans enter the sleep portion of the sleep-wake cycle, they also enter a low temperature phase of a temperature rhythm (Nelson 2011).

Biological rhythms are maintained by the use of **biological clocks**. In the instance of biological rhythms running over a 24-h period of time (circadian rhythms), there are often multiple input pathways feeding into the clock that work to **entrain** the clock and keep it synchronized to stimuli from the environment (Bear et al. 2016).

#### Input Pathway → Biological Clock → Output Pathway

The inputs/cues that govern such biological rhythms are called **zeitgebers**, from the German meaning "time giver." Light, dark, and temperature are examples of common zeitgebers. Temperature serves as a primary zeitgeber for poikilothermic (body temperature varies considerably) animals and may serve as a secondary zeitgeber for mammals and birds. Light acts as a primary zeitgeber for homeothermic (constant body temperature) animals. Other zeitgebers have also been proposed. Rabbits, which live in dark burrows, may possess unique zeitgebers governing anticipatory behaviors displayed by rabbit pups. Rabbit pups exhibit anticipatory behaviors (independent of light stimuli) of the mother returning to the burrow at regular

intervals (Jilge 1993). In this case, the precise zeitgeber is not known, but it could be a nutritional, hormonal, or social zeitgeber (Nelson 2011). Some mammals utilize maternal hormones as a first zeitgeber, while other adult animals use food/water availability, social contact, or noise-quiet cycles as zeitgebers (Wollnik 1989). The process of synchronizing endogenous biological rhythms to zeitgebers is called **entrainment**. Once entrained, an animal will still exhibit the biological rhythm in the absence of the zeitgeber, but the rhythm is "approximated." For instance, the circadian rhythm utilizes light as a zeitgeber. The circadian rhythm is entrained at 24 h when environment cues (light/dark) are present. If a subject is placed in isolation (constant light or dark environment), the circadian rhythm is still present but approximated at 22–26 h (Palmer et al. 1976). Biological rhythms not synchronized to environmental cues are called **free-running rhythms** (Nelson 2011). Free-running rhythms occur if an animal is kept in constant conditions in the absence of zeitgebers. Humans have a free-running circadian period of 24.5–25.5 h, while mice have a 23-h free-running period and hamsters are close to 24 h (Bear et al. 2016). If subjects are housed together in the absence of zeitgebers, there will be variation among individuals in the precise duration of the free-running rhythm, suggesting the subjects' biological rhythms are not synchronized to other members of the isolated experimental group. Rather, the rhythm is internally generated and maintained on an individual basis. Some zeitgebers have a modulatory effect on biological rhythms, such that the degree of intensity of the zeitgeber significantly influences the biological rhythm. Minor food restriction (leading to 15% of body weight loss) of Sprague-Dawley rats minimally disrupted the female estrous cycle. The estrous cycle persisted, but the rats exhibited attenuated lordosis behaviors (Tropp and Markus 2001). Major food restriction (leading to 50% of body weight loss) of Sprague-Dawley rats significantly delayed sexual maturation of females pups (Merry and Holehan 1979) and induced anestrus in mature female rats (Knuth and Friesen 1983).

## Exogenous and Endogenous Rhythms

For hundreds of years, biological rhythms were thought to be **exogenous biological rhythms**, or those rhythms generated by the presence of geophysical cues. The works of French astronomer and chronobiologist Jean-Jacques d'Ortous de Mairan challenged the notion that biological rhythms could only be ascribed to external factors. De Mairan observed that the tension-relaxation of a mimosa plant, which leaves open during the day and close at night, continued even when the plant was kept in darkness for days (De Mairan 1729). De Mairan did not immediately ascribe his findings to an internal clock mechanism, however. More than a century later, Swiss botanist Augustin de Candolle observed similar behavior in the mimosa plant kept in constant light conditions and noted that the leaf opening and closing cycle ran over a 22 h period of time, demonstrating a free-running biological rhythm (Coleman 1986). Over the course of the next 200 years, observations similar to De Mairan's were reported; yet, it was not until the twentieth century that scientists slowly began to accept the presence of **endogenous biological rhythms**. **Endogenous biological rhythms** involve internal timekeeping of physiological processes within an animal, meaning the rhythm is generated within the organism in the absence of environmental cues. In technical terms, endogenous rhythms are similar to active systems in which oscillations are internally generated as long as an energy supply is maintained (Aschoff 1981). Endogenous rhythms are genetically controlled; several "clock" genes have been discovered in neurons and peripheral tissues, meaning that body cells can independently generate rhythms (Bear et al. 2016). Although most biological rhythms are now thought to be endogenous, many rhythms are entrained and influenced by various zeitgebers (Reinberg and Ashkenazi 2003).

## Main Types of Biological Rhythms

There are four types of biological rhythms coupled to geophysical cues. **Circadian**,

**circatidal**, **circalunar**, and **circannual** (where the prefix "circa-" comes from the Latin root meaning "about") biological rhythms are coupled to cues from an organism's environment. **Circatidal** biological rhythms are those influenced by the tides. Marine animals often possess biological clocks governed by the ebb and flow of the high and low tides every ~12.4 h. During tidal changes, there will be corresponding changes in pressure and/or salinity which may serve as zeitgebers. The fiddler crab (*Uca pugnax*) emerges from sea-side burrows at low tide to forage and mate (Palmer 1990). Green shore crabs (*Carcinus maenas*) remain hidden until high tide to forage and mate. Interestingly, when the crabs are removed from their environments and kept in constant conditions, the Fiddler crab still exhibits heightened locomotor activity at the expected time of low tide and quiescence at high tide, at nearly 12.4 h intervals (Palmer 1990). Palmer (1990) reports that there is a 2–3% deviation from the expected 12.4 h cycle. Similarly, the green shore crab has heightened activity levels at expected time of high tide and diminished activity levels at expected time of low tide, every 12.4 h (Reid and Naylor 1990).

**Circannual rhythms** are those governed by the seasons of the year, with the entrained period length being 365.25 days. In many animals, circannual clocks are synchronized with the external environment by photoperiod (length of day), light intensity, or temperature. Many migratory birds and mammals possess circannual rhythms. When kept in constant laboratory conditions, birds showed weight gain, reproductive competence, and restlessness associated with the pre-migration time period (Gwinner 1986). The dependence of a given bird species upon seasonal cues can vary. Equatorial birds, for example, have a relatively low dependence upon photoperiod, while non-equatorial birds' circannual rhythms show a close correlation with seasonal changes and photoperiod (Wikelski et al. 2008). Many mammals exhibit circannual rhythms. Ground squirrels show annual cycles of weight gain and reproductive competence; if the temperature and food supply are sufficiently low, the squirrels will also hibernate. Yet, ground squirrels vary quite a

bit in the periodicity of circannual rhythms. They commonly range between 229 and 445 days (Davis 1976). Sheep exhibit reproductive quiescence in response to a long photoperiod ( $>13$  h), but gonadal reactivation occurs during short photoperiods ( $<12$  h). Hamsters exhibit the opposite reproductive response to photoperiod changes, with reproductive quiescence taking place during short photoperiods and gonadal reactivation during long photoperiods. The reproductive quiescence in hamsters will only persist for 18 weeks regardless of photoperiod duration (Wollnik 1989). In general, species with a “breeding season” time reproductive activities according to specific circannual rhythms.

**Circalunar rhythms** are governed by the 29.5-day lunar cycle and are mainly utilized by marine invertebrates. These rhythms may be entrained by nocturnal light levels, where the full moon represents a time of increased nocturnal light. Bristle worms (*Platynereis dumerilii*) possess a circalunar rhythm to regulate reproductive activities. Bristle worms live in large populations, and they will collectively transform into heteronereis (sexual phase) in concert with the arrival of the full moon. This allows bristle worm to coordinate mating activities and improve odds of successful mating. Such a synchronization may give the animals an evolutionary advantage by improving odds of reproductive success (Zantke et al. 2013). Ant lions (*Myrmeleon obscurus*) are predatory insects which build extensive pits in order to catch prey. The ant lions build larger pits during the full moon than new moon. When ant lions are laboratory-kept in constant conditions, ant lions still build larger pits during the full moon (Youthed and Moran 1969). Youthed and Moran (1969) also noted that ant lions are most active 4 h after moonrise (solar-day rhythm) and proposed that the pit-building behavior represents the interaction of a solar-day and circadian rhythm. This evidence suggests that organisms likely possess multiple types of biological clocks.

**Circadian rhythms** are the most widely studied and best understood of all biological rhythms. Circadian, from the Latin roots *circa* (about) and *diem* (day), rhythms are those relying upon a 24-h light/dark cycle, with light serving as a zeitgeber

(Bear et al. 2016). Many animals regulate their activities (i.e., feeding, mating) and internal physiological processes (i.e., hormone secretion) over a 24-h time period. Animals are often classified according to when their highest activity levels occur relative to the day-night cycle. **Diurnal** animals (e.g., ground squirrels, many primates, chickens) are active during the day, while **nocturnal** animals (e.g., raccoons, owls, hamsters) are active at night. **Crepuscular** animals (e.g., deer, rabbits) are active at dawn and dusk, while **catheimeral** animals (some lemurs and howler monkeys) exhibit irregular activity at any time of night or day (Engqvist and Richard 1991). The majority of mammals are classified as nocturnal. A study showed that of 2,966 species of non-threatened mammals, 70% were nocturnal, 19% were diurnal, 9% were catheimeral, and 2% were crepuscular (Bennie et al. 2014).

In mammals, the circadian rhythm is thought to be entrained by input to the suprachiasmatic nucleus (SCN) of the hypothalamus, which projects to the pineal gland. In vertebrates, light enters the eyes and stimulates specialized photoreceptors within the retina. The axons of retinal ganglion cells form the retino-hypothalamic tract which projects from the retina and synapses on the dendrites of SCN neurons (Kandel 2013). Several studies point to the SCN as the predominant circadian oscillator. First, bilateral lesion of the SCN eliminated circadian-controlled behaviors and physiology (Nelson 2011). Second, destruction of the SCN and retino-hypothalamic tract in golden hamster eliminated or modified entrainment to night-day cycles. The hamsters exhibited free-running light cycles and exhibited abnormal circadian rhythms for drinking and activity (Rusak 1977). Third, transplantation of SCN tissue into a recipient caused the recipient's circadian rhythm to match that of the donor (Lehman et al. 1987). Fourth, each cell in the SCN is autonomous and generates its own specific circadian rhythm (Hastings et al. 2003). SCN neurons also exhibit light sensitivity, with broad receptive fields exhibiting high sensitivity to light intensity, as opposed to motion or orientation (Bear et al. 2016). Remarkably, the SCN neurons are able to generate circadian rhythms in the absence of

action potentials. Communication between cells in the SCN is poorly understood, but generation of the circadian rhythm is not dependent upon action potentials or chemical synaptic transmission (Bear et al. 2016; Kandel 2013). “Clock genes” are likely responsible for the circadian behavior of the SCN neurons (Bear et al. 2016). The SCN has output pathways to other nuclei within the hypothalamus, the midbrain, and the pineal gland. The SCN is not the circadian oscillator for all animals. In birds, the pineal gland serves as both a photoreceptor and circadian oscillator. Removing the pineal gland from these animals leads to disruption of circadian rhythms (Takahashi et al. 1989). Individual cells also possess a circadian clock that is active when isolated from the body and grown in culture. The cells’ circadian rhythms are not expressed *in vivo*, as the cell is then under the control of the SCN clock. The SCN exerts its influence on cells of the body largely by way of the autonomic nervous system (Bear et al. 2016). The autonomic nervous system’s central regulation network includes other hypothalamic nuclei (see “Vaso-vagal stimulation” entry) that receive innervation from the SCN.

In humans, circadian rhythms likely play a role in mood regulation. Clock genes are localized to neurons of the ventral tegmental area, amygdala, nucleus accumbens, and prefrontal cortex – structures of the brain’s reward system. Additionally, dopamine is a neurotransmitter of the brain’s reward pathways whose levels oscillate on a circadian basis within the nucleus accumbens. Many studies demonstrate that dopamine neurotransmission is diminished in major depression (Dunlop and Nemeroff 2007). If the attenuated dopamine neurotransmission is due to circadian arrhythmia, therapies targeted at re-synchronizing the clock may be effective. Some evidence suggests this may be the case. Sleep deprivation has been shown to improve depressive symptoms in 40–60% of patients. Similarly, bright light therapy and lithium are other effective treatments for depression. Each of these therapies evokes changes in circadian rhythm (Albrecht 2013).

Some biological rhythms have no known geophysical cue. **Ultradian rhythms** are those shorter than circadian rhythms (but higher frequency),

while **infradian rhythms** are those longer than circadian rhythms (but lower frequency). However, ultradian and infradian rhythms do not have specific geophysical cues, unlike circadian, circatidal, circalunar, and circannual rhythms. The rapid eye movement (REM) sleep cycle, lasting approximately 90 minutes, is an example of an ultradian rhythm. Hormone secretion patterns, such as those for corticosterone and Luteinizing Hormone, also follow ultradian rhythms (Wollnik 1989). Ultradian rhythms are repeated over the course of a day. Like ultradian rhythms, infradian rhythms do not have specific geophysical cues. The female estrous cycle, which lasts for 4 to 5 days in rats and hamsters, is an example of an infradian rhythm (Nelson 2011). All biological rhythms, whether they rely upon geophysical cues or not, are important for the appropriate timing of behaviors and physiological processes to meet the needs of an organism.

## Biomass

Santosh Kumar Mishra  
Biotechnology, IMS Engineering College,  
Ghaziabad, India

## Synonyms

Biological material derived from living or recently living organisms; Total mass of living matter

## Definition

Biomass is the renewable organic material obtained from agricultural product, animal, and municipal wastes and can be used as a source of fuel or energy.

Biomass is an organic matter produced directly or indirectly by living organisms and probably the largest energy source after the sun. The biomass in plant matter is produced by the process of photosynthesis in which carbon dioxide and water from the environment are converted into carbohydrates (sugars, starches, cellulose and lignin) by using energy from sunlight. Lignocellulosic biomass have been recognized as a potential sustainable source of mixed sugars for fermentation to biofuels and other biological products of industrial importance. Several technologies have been developed during the past that allow this conversion process to occur, and the clear objective now is to make this process cost-competitive in today's markets (Himmel et al. 2007). Biomass feedstocks that can be used as a potential source of energy include agricultural crop residues, forestry residues, algae, wood processing residues, municipal waste, agro-industrial wastes, sorted municipal solid waste, etc.

Due to increasing demand of energy resources and overexploitation of fossil fuels that impacts on the global warming, the use of renewable energy resources is becoming necessary for sustainable growth. Most common form of renewable energy is the biomass and widely used as alternative

energy resources in the worldwide in the recent few decades. Significant attention has been focused on identifying suitable and efficient biomass sources that can conveniently provide high and efficient energy outputs so that the conventional fossil fuel energy sources may be replaced. The type of biomass required is largely determined by the energy conversion process potentialities and the form in which the energy is required (McKendry 2002). However, energy can be produced by biomass, using various biological, physical, and chemical processes. Conversion of complex biomass to biogas has been of great interest to the scientific community in recent years. Several recent studies have been conducted to understand the anaerobic digestion process and to characterize responsible microbes for the possible biochemical conversions (Azman et al. 2015).

The complete reliance on fossil fuels is recognized as unsustainable throughout the world. Due to emission of significant quantities of greenhouse gases associated with fossil fuel exploration and combustion, rapid declining of fossil fuel reserves is observed in various countries. Algal biofuels also called third-generation biofuels appear to be promising in supplementing sustainable and complementary energy resource. Algae-based biomass can be converted into various biofuel products, such as hydrogen, biodiesel, bioethanol, as well as biogas through different processes such as biochemical and thermochemical processes. Thermochemical conversion process is considered as efficient and economical in comparison to existing problems associated with biochemical conversion such as higher reaction time, low conversion efficiency by microbes and enzymes, as well as high production costs (Raheem et al. 2015).

The dual application of microalgae for phycoremediation and biomass production for sustainable biofuel production is a feasible option. Microalgae as an environmentally friendly renewable feedstock can be processed into biofuels via various conversion technologies such as algal lipid upgrading, liquefaction, pyrolysis, gasification, and bioethanol technology. As a unique chemical reaction, pyrolysis of microalgae yields useful chemicals like light olefins, alkanes, and

syngas, as well as the bio-oils with less oxygen, more hydrocarbons, and higher gross heating values than the bio-oils derived from cellulosic biomass (Rawat et al. 2011). Designing novel catalysts and optimizing culture conditions for the growth of algae and the selective conversion of microalgae into fine chemicals may increase the effective use of microalgae and the economics of the process. Due to the advancement of scientific innovations and technology catalytic pyrolysis, technology has the potential to process microalgae into biofuels as well as some other industrially important fine chemicals (Yang et al. 2019).

## Biosociology

Allan Mazur

Syracuse University, Syracuse, NY, USA

Like its better known cousin sociobiology, introduced by entomologist E.O. Wilson in 1975 (Wilson 1975), *biosociology* refers to the modern study of biology as it relates through an evolutionary framework to social behavior. Sociobiology has many detractors who argue that it revives biological determinism, sexism, racism, and social Darwinism. Some prefer the term “biosociology” because it avoids the negative connotations of sociobiology and has importantly different slants on theory and research methodology.

When it was formulated and popularized, sociobiology presented issues uncomfortable to modern students of human behavior. It focused on *ultimate* causes of human nature, ignoring *proximate* mechanisms through which behavior directly operates. An example is the sociobiological theory of sex differences in mating strategy. Males produce offspring with an ejaculation; females invest a long period of pregnancy and nursing. So males maximize genetic fitness (i.e., the representation of their genes in succeeding generations) by spreading their genes among many females, whereas females are selective, limited their pregnancies to the finest available males, preferably those committed to child support. Emphasis is on evolution through the distant past, ignoring those recent influences of psychology and culture, the explanatory currency of the social sciences. Ultimate theory cannot explain why one culture is polygamous, another monogamous, why marriages in some societies are arranged by parents and in others by romantic attraction, and why divorce and birth rates vary over time and place.

Some of sociobiology’s claims defy common observation. Most social scientists do not maximize their genetic fitness, instead limiting their children to two or less, and some “waste” resources by adopting unrelated infants.

Entomologist Wilson likened human homosexuals to sterile ant workers that maximize fitness not with their own offspring but by nurturing the fitness of siblings.

An offshoot of sociobiology, called “evolutionary psychology,” fixed some of these issues. Its leaders, themselves students of human behavior, were interested in a reformulation that avoids implausible statements about people. Their most important innovation was to reintroduce proximate causation in the form of an “adapted” brain. Social scientists of the 1960s thought of the brain as John Locke’s blank slate, upon which a particular culture and language were written during a period of socialization. Evolutionary psychology endowed the brain with innately specialized mechanisms for parenting, emotional communication, kinship, mate choice, sex, aggression, danger avoidance, mate guarding, childcare, and so on (Barkow et al. 1992). Most notable is the Chomskyan mechanism for language, present before birth though requiring a period of learning to accommodate any particular language.

Evolutionary psychologists emphasized that our minds have evolved, not our disembodied behaviors: evolution produced the mind, and the mind produces behavior. This is a clever modification of sociobiology’s exclusive focus on ultimate causes. With a language-speaking mind as a proximate mechanism, one can incorporate learning, socialization, and cultural differences – all notions that are important to social science but excluded from sociobiology.

The adapted mind eliminates the unacceptable tenet that humans maximize inclusive fitness. Instead our actions are explained by the calculations of these minds, which balance, say, a diabetic’s primitive urge to eat sweets with her physician’s advice to abstain. Married couples, whom sociobiologists required to have as many children as possible, are allowed by evolutionary psychologists to weigh their reproductive urges against the costs of a college education or the demands of a two-career family. The male mind still desires sex with many women, but the penis may be held in check by moral strictures or caution about venereal disease or fear of discovery by

a wife. The female brain still seeks long-term commitment from a dominant male, but actual behavior may depend as well on availability of birth control pills and a desire for even temporary closeness and sexual pleasure.

Evolutionary psychology, having solved some of sociobiology’s inadequacies, went on to produce some of its own. Its adapted mind is a postulate; its various modules are conceptualizations without empirical verification.

Perhaps, too, evolutionary psychology focuses too narrowly on humans, ignoring our primate cousins, who seem to share with humans a broad primate model of behavior. Consider, for example, the theory of male and female mating strategies, which should apply to apes as well as humans. Male gorillas and orangutans seek multiple mates, while females are usually limited to a single male, consistent with the theory. But gibbons and siamangs are monogamous. Among chimpanzees, both sexes mate with multiple partners. Among bonobos, females freely seek sexual relations with males and other females. Thus the hypothesized sex difference is not apparent in most apes nor in those most closely related to humans, the chimpanzees, casting doubt on the theory’s underlying reasoning.

Despite its shortcomings, by introducing a thinking mind that is capable of being influenced, evolutionary psychology took a long stride toward reconciling natural selection with sociology, at the same time eliminating implausible claims from sociobiology. But the ideological divide between sociology and natural selection remains wide. Social Darwinism in its various incarnations has too strong a taint, trying to justify why some people are inferior to others.

Biosociology avoids speculations about ultimate causes conjectured about the unknowable past. Its focus is on proximate causes, for example, the neurohormonal mechanisms underlying human behavior. Biosociology emphasizes that human behavior follows a primate pattern and therefore values comparative studies of other primate species, whereas analogs with insects, birds, and fish are too distant to be useful (Mazur 2005, 2007). Biosociology’s research methods are diverse but usually have a tight link to theory.

Biosocial hypotheses should be falsifiable by practical empirical means.

Few sociologists have requisite training in biology, so most relevant research is conducted in neighboring disciplines including social psychology, primatology, anthropology, genetics, and behavioral economics. Primatology has had the greatest impact, leaving no doubt that human behavior in face-to-face groups fits the general pattern of higher primates – with the supremely important addition of language-based cultures. The hormones testosterone and cortisol have become important variables in biosocial studies of dominance in face-to-face groups and of antisocial behavior (e.g., Carré et al. 2013). Currently there is much interest in a “dual-hormone” hypothesis whereby testosterone and cortisol jointly regulate social dominance (Mehta et al. 2010). Brain imaging techniques are showing how different areas of the brain respond to social engagement (Lieberman 2013). Behavioral genetics demonstrates that some personality traits, long thought to be determined by early childhood socialization, are strongly inherited and highly correlated in identical twins raised apart. Population geneticists, tracing specific variants of the Y chromosome in men and mitochondrial DNA in women, infer the migratory paths of major ancestral groups of *Homo sapiens* during the past 50,000 years (Wells 2006). This sampling of findings barely suggests the potential of biology to revise our understanding of human social behavior.

## Biparental Care

Ádám Z. Lendvai

Department of Evolutionary Zoology and Human Biology, University of Debrecen, Debrecen, Hungary

## Definition

Biparental care is when offspring is cared for by both the male and the female parent.

## Introduction

Parental care is any form of behavior or resources provided by a parent that enhances the fitness of its offspring and that evolved (and is currently maintained) for this function. Parental care may include behavioral traits, such as incubation, food provisioning, or protection against predators, but it may also include nonbehavioral traits, such as gestation or viviparity. Many forms of parental care are costly for the parents, i.e., decreased parental survival and/or future reproduction. For example, female common eiders (*Somateria mollissima*) incubate continuously in the harsh Arctic until the eggs hatch, and she does not

even leave the nest for foraging, therefore fasting throughout the incubation period, with serious physiological and life-history consequences. Even if not that dramatic, subtler forms of parental care are also costly. For example, increasing the brood size by two nestlings in kestrels (*Falco tinnunculus*) results in an increase in metabolic activity and a reduction of parental survival. The benefits of parental care are shared between the parents (both gain fitness benefits from the increased survival of the common offspring), but these costs affect the parents individually, therefore there is an almost inevitable conflict over parental care, where each parent prefers the other to have the greater share of the work.

### Evolutionary of Sex Roles and Biparental Care

The resolution of this conflict often results in uniparental care (i.e., when only one parent cares for the offspring), and typically the female is the sex that provides more care. These conventional sex roles were corroborated by large-scale phylogenetic comparative analyses (Janicke et al. 2016). Angus John Bateman (1948) discovered that in the fruit fly (*Drosophila melanogaster*) reproductive success is more variable in males than in females and showed that reproductive success increases sharply with the number of mates in males, whereas this effect is less evident in females. He argued that the reason behind this observation is that eggs are more expensive to produce than sperms, therefore the limiting factor for the lifetime reproductive success will be different for the sexes: for females, it is resources that they can convert into eggs, while in males it is access to females. Based on these ideas Robert Trivers (1972) formulated the concept of parental investment that incorporates the costs associated with parental care and defined it as any form of behavior towards an individual offspring that increases the offspring's survival (and hence reproductive success) at the cost of the parents' ability to invest in other current or future offspring. Parental investment theory explains the evolution of sex roles and predicts that if one sex has considerably higher parental investment than the other, then member of the

former, less investing sex (typically males) will compete for the members of the other sex (typically females). Parental investment theory therefore also explains the exceptions from the conventional sex roles, e.g., in the case of phalaropes (*Phalaropus* sp.) that show so-called sex-role reversal, where females are bigger and more colorful than males, compete extensively for males who in turn provide all parental care for the offspring. Recent work, however, has shown that the direction of causality can act in the opposite way, where the sex that experiences stronger sexual selection during mating will be selected to provide less parental care (Kokko and Jennions 2008). Mating and parental care systems therefore evolve together.

Phylogenetic predisposition also has a major role in the evolution of parental care. For example, while biparental care is the norm in birds (90% of species), it is rare in mammals (5% of all species) and biparental care is generally rare in invertebrates. This discrepancy may reflect the differences in how different taxa raise their young. Invertebrates can often do little to efficiently protect their offspring, or they are selected to compensate the high rates of offspring mortality with the production of large amount of eggs. While in mammals only females lactate, in birds both males and females can efficiently provision and guard the chicks. Therefore, the sexual asymmetries in the ability of providing care are important drivers of parental care systems, but sexual conflict over parental care also promotes the evolution of sex differences in care and the ability to care.

### Evolutionary Alternatives: Remating Opportunities

Even when both parents are equally likely to provide care for the young, sexual conflict over care may arise from differing mating opportunities. When one parent has much better probabilities to find another mate than its partner, then this sex will be selected to desert the current brood and reproduce with another partner. In birds, for example, precocial species, where one parent is more likely to raise the young alone, and the sexes are often equally successful in doing so, both

males and females respond to increased mating opportunities by altering their level of care. Altricial birds, however, where the young need more provisioning, do not show these relationships (Olson et al. 2008). In cases where sexual conflict over care is intense and both sexes have good remating opportunities, the deserted parent may also decide to leave. For example, in the Penduline tit (*Remiz pendulinus*), a Eurasian passerine, during egg laying either the male or the female can desert the brood and only the other parent will incubate and raise the young. However, 30% of the eggs are deserted by both parents.

### Optimal Parental Investment in Biparental Care

In many cases, however, parents do cooperate in raising the young, but there is also conflict about how much care to provide. Several theoretical models have been proposed to predict how conflict over parental care may be resolved. These models differ in their assumptions regarding behavioral strategies available to parents and consequently the predictions they offer when a parent increases or decreases parental care. The first type of model is the “sealed-bid model” (Houston and Davies 1985) which assumes that optimal parental effort by each sex will be achieved through evolutionary time, where each parent uses a fixed level of effort given its partner’s effort. Later models extended this framework to allow for a behavioral negotiation between the parents. These “negotiation models” predict that when one parent decreases its effort, the other parent is predicted to compensate by increasing their own effort, but this compensation has to be incomplete for this model to be evolutionarily stable (McNamara et al. 2003). A third type of model, the “information model” (Johnstone and Hinde 2006) is built upon the negotiation models by assuming that when parents have only incomplete information about the brood value and need, they use their mate’s parental effort as a cue in determining the level of parental care needed to optimize reproductive success. This model may predict different outcomes (compensation or matching response, i.e., when one partner’s decrease or increase in parental care is mirrored by a similar

change from its partner) depending on the information about brood value and need available for the parents. Finally, in the “perfect family” model (Akçay and Roughgarden 2009) parents are assumed to be able to communicate directly to coordinate their parental efforts. This model predicts a matching response when one parent increases its parental effort.

### Division of Labor

Sexual conflict can be reduced and biparental care can be stable if parents use division of labor and specialize in different parental roles. For example, one of the rare examples of invertebrate biparental care also shows division of labor between the sexes. Males of *Parastizopus armaticeps*, a nocturnal desert dwelling beetle, dig, guard and extend a special breeding burrow, while the female is foraging on the surface for limited food sources which she brings back to the burrow for the developing larvae (Rasa 1998).

### Conclusion

Taken together, biparental care is affected by the combination of phylogenetic, ecological, and demographic factors. In general, biparental care is selected for in species where both parents are able to increase the offspring’s survival in an efficient way, when ecological conditions allow for and development of the offspring require both parents to care, and when the fitness benefits of parental care outweigh the fitness gained by increased survival or reproductive success by desertion. Even when biparental care is stable, sexual conflict may shape the amount of parental care provided, and when sexual conflict is intense, offspring may be better off with a single parent.

## Bipedalism

Daniel Schmitt<sup>1</sup>, Laura Gruss<sup>2</sup> and Angel Zeininger<sup>1</sup>

<sup>1</sup>Department of Evolutionary Anthropology, Duke University, Durham, NC, USA

<sup>2</sup>Department of Biology, Radford University, Radford, VA, USA

## Definition

A type of walking and running gait in which the two hind limbs support the entire body weight.

Bipedalism involves an erect (nonsprawling) posture and a striding (sequenced between right and left) footfall pattern. Bipedalism is used by birds, fast running reptiles, primates, and, in its obligate form, humans and our fossil hominin ancestors.

## Bipedalism: An Unusual Locomotor Form

In George Orwell's *Animal Farm*, the revolutionary animals who overthrew their human masters famously wrote out a sign that said “Four legs good, two legs bad.” They had identified the singular defining character that separated them from their oppressors. They were right: bipedalism defines our species and the large group of fossil human ancestors that we call hominins.

Defining bipedalism seems like an easy task at first. Humans (and birds) use two legs for walking (a gait in which there is always at least one foot on the ground and footfalls alternate between right and left sides) and running (footfalls alternate but there is an aerial phase with no feet on the ground). This unusual gait evolved in our human lineage over a period of at least 6 million years, perhaps from an ancestor that practiced a slightly different, non-obligate (facultative) form of bipedalism (see Schmitt 2003 for a review).

Bipedal walking and anatomy take time to develop in each of us as well. During childhood we develop specialized anatomy and motor control to execute this gait. Its fully adult form doesn't emerge until 9 years of age (Sutherland et al. 1980), going through many stages prior to that. So to precisely define this gait and its associated anatomical and neurological features, we need to look at its biomechanics, evolution, development, and the ways in which human bipedalism compares to that of other animals, especially other primates.

## Bipedalism in Modern Humans and Other Primates

During walking and running, humans use an upright posture in which the lower limbs are held in line beneath an erect upper body rather than sprawling to the side (Fig. 1a, b). We also use

Bipedalism, Fig. 1 (continued)

a striding gait that involves a sequenced pattern of footfalls: putting one foot in front of the other, as opposed to hopping or bounding as in kangaroos. At the beginning of stance phase (Fig. 1a, b), the hip is flexed, and the knee is extended (a pattern different from that of primate quadrupeds where the knee is relatively flexed at foot contact) with the lower limb out in front of the body. The ankle is dorsiflexed (foot at or less than  $90^\circ$  relative to the leg) when the heel makes initial contact with the ground at heel strike. It is worth noting that heel strike is a pattern not seen in all primates; it is present only in large-bodied apes (Schmitt and Larson 1995). Humans walk with relatively stiff legs, in which the hip sweeps a wide arc over a knee that flexes only slightly, and the ankle remains dorsiflexed through midstance. The ankle becomes plantarflexed (foot to leg angle that is larger than  $90^\circ$ ) at the end of stance phase so that toe-off occurs as body weight is pushed forward off the big toe (hallux) (Fig. 1a, b). Thus, the center of pressure (the anchor point of ground reaction forces) follows a proximal to distal and lateral to medial “rollover” beneath the foot from the heel to the big toe.

Modern human walking is considerably more efficient than that of any other bipedal primate and many quadrupeds (see Sockol et al. 2007; Demes and O'Neill 2013). By walking with stiff and extended legs, humans “vault” over each support leg successively, and our center of mass (COM) follows a cyclical rising and falling path from heel strike to toe-off. This “inverted

pendulum” style of movement efficiently recycles potential and kinetic energy during each stride, reducing muscular effort considerably (Fig. 1a–d) (Schmitt 2010). Although 65% of the energy needed for forward progress is recovered through this exchange process, additional muscular work is required (Cavagna et al. 1977). That additional energy needed to move forward is provided by plantarflexion of the ankle, made possible by the loading of the entire foot from heel strike to the powerful hallucial toe-off, during which the foot shifts from a role as shock absorber and energy absorber (see Griffin et al. 2015) to a stiff lever.

During running, in contrast, the knees flex deeply during the middle of the foot contact phase, causing the COM to descend in such a fashion that its movement mimics a bouncing ball (Fig. 1b, d) and, at high speeds, there is sometimes no heel strike (Hatala et al. 2013). There is no pendular energy exchange in running, though some energy is stored and returned in the ligaments of the foot (see Griffin et al. 2015). In a slightly different mechanical perspective, some have argued that the cost of locomotion is dictated by changes in direction of the COM from generally downward to generally upward, a pattern that occurs in both walking and running using a spring-loaded pendular model (Bertram 2016) (Fig. 1d). The costs of these redirections (often called collisions) is mitigated by the number of collisions, the number of feet involved in the collisions (two during a walk, one during a run),

**Bipedalism, Fig. 1** The mechanics of an adult human bipedal walking stride. (a) Stance phase begins as the limb (in black) makes initial contact with the ground at heel strike. At heel strike, the contralateral limb (in white) is still on the ground, so this portion of stance phase is called double support. At heel strike, the knee is very extended, the ankle is dorsiflexed, and the center of mass (COM, red line) is low. The knee flexes slightly to absorb impact forces as the contralateral limb toes off (10% of stride duration). At midstance (23% of stride duration), the knee is fully extended, the foot is flat on the ground, and the COM is high. Following midstance, the knee begins to flex, and the heel elevates as the ankle plantarflexes in preparation for a powerful hallucial toe-off, at which time the COM is low again. Following toe-off, the hip and knee

flex, and the ankle dorsiflexes so that the toes clear the ground as the limb swings during swing phase. Swing phase, and one complete stride, ends when the heel strikes a second time. (Image modified from Mummolo et al. 2013). (b) The rise and fall of the COM allows for efficient exchange of potential energy (large dash line) and kinetic energy (small-dash line), reducing the fluctuations of the total energy of the COM and reducing muscular work. (Images from Queen et al. 2016). (c) Walking and running differ in leg stiffness, with running showing deep knee flexion in stance phase. (Images from Muybridge 1955). (d) The COM in running behaves more like a bouncing ball compared to the inverted pendulum pattern of walking and does not facilitate exchange of potential and kinetic energy  
RHS = Right Heel Strike.

and path-matching of the COM velocity and substrate reaction forces that lead to pseudoelastic collisions.

## Bipedalism in Other Primates

Other primates can use bipedal gaits on the ground and in the trees. Almost all primates can stand easily on two legs, and many walk upright with sequenced footfalls when needed. But those primates that move bipedally do so in an occasional (facultative) way rather than in an obligate way as is the case for humans. Unlike humans, all nonhuman primates adopt deeply flexed hip postures and deeply yielding knee joints during bipedal walking and, to the extent that they can be said to do so, running (see Schmitt 2003 for a review). Thus, in walking and running in nonhuman primate bipeds, the COM is often flat or follows an arc downward between touch down and midstance and then upward again so that the COM and leg follow the path of a spring mass system or bouncing ball, as in human running. However, some chimpanzees and many macaques with long-term training in bipedalism adopt relatively stiff gaits (see O'Neill et al. 2018 for a review).

The contexts in which nonhuman primate bipedalism occurs vary across species and are sometimes the result of anatomical restrictions that preclude the use of quadrupedalism. Gibbons, with their exceptionally long arms, do not have a quadrupedal gait and must use bipedalism when moving on top of large branches or on the ground. Sifaka, highly specialized leaping lemurs from Madagascar, face the opposite problem – long lower limbs but short upper limbs with large hands – and can only rarely walk quadrupedally (Wunderlich and Schaum 2007). So when they are on the ground, they walk – or, more commonly, hop – bipedally with a sequence of footfalls that has been described as a “bipedal gallop” (Wunderlich and Schaum 2007). COM patterns of sifaka bipedal running gaits are similar to those of human gaits, but the COM during their walking gaits follows a flattened path, and they use deep knee yield during stance. South American capuchin monkeys that walk on the

ground bipedally when carrying tools also have gaits that approach, from a mechanical perspective, that of humans, though with some clear distinctions (see Demes and O'Neill 2013). During walking, capuchins show a bent-hip and bent-knee gait with a COM trajectory with its lowest point at midstance, and, as with other primates, they lack a powerful hallucial toe-off (see Demes 2011 for a review). Nor do capuchin monkeys recover energy from COM fluctuations, a pattern also seen in chimps and that is in contrast to that of humans (Demes and O'Neill 2013; Kimura 1996).

## Anatomical Features Associated with Obligate Bipedalism and Their Evolution

Nonhuman primates that use facultative bipedal gaits show limited musculoskeletal adaptations for bipedal motion, with their skeletal adaptations reflecting their primary locomotor behavior. But humans, with their commitment to bipedalism, have undergone a fundamental reorganization of the musculoskeletal system that reflects a complex compromise between varied and competing selective pressures (see Aiello and Dean 2002 for an overview). Here we concentrate on lower limb features, particularly those that were subject to interlocking and potentially conflicting demands of thermoregulation, and, in the case of the pelvis, obstetrics.

Hominin adaptations to obligate terrestrial bipedalism evolved in a mosaic fashion, evident by 4.4 million years ago (mya; Lovejoy et al. 2009a) but possibly beginning as early as 6 mya. Based on current fossil evidence, the pelvis was among the first structures to be altered for bipedalism (Lovejoy et al. 2009b). A major feature of the human pelvis that allows efficient bipedal walking is the reorientation of the iliac blades to face sideways, instead of backwards as in apes, resulting in a bowl-shaped pelvis. The human configuration allows the lesser gluteal muscles, which run from the outside of the iliac blades to the top of the femur, to efficiently balance the pelvis and upper body over a single support leg during locomotion. The orientation of the iliac

blades in humans also permits rotation of the pelvis counter to the rotation of the thorax during locomotion and thus allows the pelvis to contribute to a long stride length (Inman et al. 1981; Rak 1991; Gruss et al. 2017). Chimpanzees, in contrast, limit counterrotation of the pelvis and thorax and walk with a swaying gait and/or with their upper limbs to the side for balance (see O'Neill et al. 2018). The human pelvis has also been shortened from top to bottom compared to that of apes, which further improves our balance in upright stance (Fig. 3a–d).

Although these changes in the hominin pelvis facilitated obligate bipedal locomotion, they decreased the size of the birth canal (Gruss and Schmitt 2015). This is unlikely to have been an issue in early hominins, with their small-brained babies, but causes well-known difficulties with

childbirth in modern and probably fossil *Homo*. Early hominins may have compensated somewhat by maintaining a relatively broad pelvis (both the birth canal and the distance between the iliac blades), a morphology seen in australopiths as well as premodern *Homo* (Fig. 3). It was long assumed in paleoanthropology that a wide pelvis would have been detrimental to locomotor efficiency, but recent experimental studies have shown that greater pelvic breadth actually provides energetic advantages in bipedal walking, particularly while carrying infants (Wall-Scheffler and Myers 2017).

Humans have long lower limbs relative to apes (Fig. 2), and this contributes greatly to the energetic efficiency of our bipedal walking and running by increasing stride length. Longer strides allow us to travel a given distance using fewer

locomotor posture of *Australopithecus afarensis*, *Homo erectus*, and a modern human. (Image modified from Gruss and Schmitt 2015)

steps, minimizing the number of costly collisions associated with changing the trajectory of the center of mass. Elongated lower limbs were not present in the earliest hominins. Essentially modern limb proportions evolved in *Homo erectus*, just after 2 mya, along with a number of other traits of the feet including short toes and a robust arch that may be adaptations for long-distance walking and running (Holowka and Lieberman 2018) (Fig. 3e)

The femur and tibia in humans and other hominins are also adapted for upright stance and bipedal locomotion (see Stern and Susman 1983; Lovejoy et al. 2009a, b). Compared to quadrupedal primates, hominins have larger joint surfaces in the hip and knee for bearing the weight of the entire upper body, and the femoral and tibial shafts, in addition to being longer, are more robust. The femur slants inward down from the

hip toward the knee (the *bicondylar angle* of the femur), meeting the tibia at an angle when viewed from the front. This configuration of the joint is known as the *valgus knee* (Fig. 2b). In other primates, the femur and tibia are much more parallel. The human bicondylar angle positions the knee and foot more directly under the body's center of mass, acting with the lesser gluteal muscles to improve balance during single-legged stance (Aiello and Dean 2002). In modern humans, the valgus knee develops during childhood only with habitual bipedal walking; in children who cannot walk, the typical bicondylar angle is not present (Tardieu and Trinkaus 1994). The knee is not well represented in the hominin fossil record before the Plio-Pleistocene, but a humanlike bicondylar angle of the femur is clearly evident among australopiths (Stern and Susman 1983).

The human foot has been reorganized from a mobile and grasping appendage like that of other primates to a non-grasping rigid lever (see Holowka and Lieberman 2018, for a recent review). Although humans are not the only primates to use a heel strike (chimpanzees, gorillas, and orangutans have also been observed to use a form of heel strike; Schmitt and Larson 1995), our large heel bone (calcaneus), with its associated cushioning fat pad, is thought to be adapted to withstand high impact forces associated with a bipedal heel strike. The human foot is unique in having transverse and medial longitudinal arches. The longitudinal arch is supported by ligaments (spring and other plantar ligaments) and a plantar aponeurosis running from the calcaneus to the base of the phalanges (toes). The plantar aponeurosis is stretched to store energy when the Achilles tendon pulls on the calcaneus to raise the heel following midstance, which raises the medial longitudinal arch and causes the bones of the midfoot to come in close contact with each other (essentially locking the midfoot and transforming the foot into a rigid lever). This mechanical configuration is known as the windlass mechanism (Griffin et al. 2015). Compared to other primates, humans have relatively short toes and a robust hallux that is in line with the foot and the other toes (adducted). An adducted hallux precludes grasping with the foot but allows for a powerful hallucial toe-off during human bipedal walking.

## Development of Bipedalism

The mechanics of human bipedal locomotion mature gradually (see Sutherland et al. 1980 for a review). Many infants crawl before passing through an assisted bipedalism stage in which the hands are used to help the infant balance (referred to as “cruising”). Independent walking without the aid of the hands begins around 1 year of age. At the onset of walking, there is co-activation of the calf and shin muscles (tibialis anterior, soleus, and gastrocnemius) during walking, preventing ankle dorsiflexion at the end of swing phase (Myklebust 1990). Young walkers

thus lack a true heel strike and the foot touches down with either a flat foot (plantigrade) contact or with the forefoot (toe-walking). In flat foot contact steps, the center of pressure is most often located anterior to the calcaneus at touchdown. Weight is distributed across the entire plantar surface of the foot including the medial foot pads, reducing pressure loads and shear forces acting on any one segment of the foot. Plantigrady increases the area of the base of support beneath the foot and, along with a relatively wide stance, allows for a high degree of stability. This is likely an important feature in toddlers, who lack balance control following small perturbations.

By the end of the first year of independent walking, peak pressures increase beneath the hindfoot at the beginning of stance, decrease beneath the midfoot, and increase beneath the forefoot at the end of stance. Lateral to medial rollover of the center of pressure throughout stance phase is present although a longitudinal arch is still absent until 4–6 years of age (Bertsch et al. 2004). Single limb stance phase in toddlers is very short, a phenomenon Sutherland et al. (1980) attribute to an inability to control the ankle plantar flexors (gastrocnemius and soleus) at less than 2 years of age. Around the beginning of the second year of independent walking, the ankle is dorsiflexed during swing phase and mature control of the ankle dorsiflexors (primarily tibialis anterior) and plantar flexors allows for an initial heel contact. By 2 years of age, the ankle plantar flexors are finally used in preparation for a distinct toe-off. The remaining suite of gait parameters that are indicative of mature human bipedalism (including an extended knee in the support leg at midstance, a flexed knee and dorsiflexed ankle in the swing leg during swing phase, and reciprocal arm swinging throughout the gait cycle) continues to mature until around 9 years of age.

## Why Bipedalism Evolved

The selective factors that drove the evolution of obligate human bipedalism (and for that

matter bipedalism in other lineages like birds and dinosaurs) remain an area of discussion and contention. As is often the case, natural selection forced adaptive trade-offs as bipedalism evolved. Bipedalism is in many ways less stable than quadrupedalism, but it may enhance maneuverability, frees the hands, can be practiced very efficiently, and may provide some thermoregulatory benefit. But many of these advantages accrue even when bipedalism is used occasionally by animals who are primarily adapted to quadrupedal locomotion. For example, as discussed above, bipedalism allows some primates (e.g., gibbons and sifakas) to move about effectively on the ground when their adaptations for arboreal locomotion preclude terrestrial quadrupedalism. In other cases, facultative bipedalism facilitates load carriage, vigilance, or sexual and aggressive displays (e.g., capuchins and great apes) (see Fleagle 2013 for a review).

So why give up quadrupedalism to become obligate terrestrial bipeds, instead of using bipedalism on an as-needed basis as so many living primates do? There is still no clear answer to this question (see Fleagle 2013, for a complete review), although many theories have been proposed. The most common and enduring idea is that bipedalism evolved in human ancestors to free the hands for carrying infants, food, or water, to gather food, or to use tools or weapons. Alternatively, bipedalism may have evolved to help early hominins see over tall grass or travel more efficiently between food trees, especially in an increasingly open habitat. Bipedal walking may have limited sun exposure (compared to quadrupedalism), and thus afforded early hominins a thermoregulatory advantage. But all of the above may be served by facultative bipedalism. Still others argue that, like gibbons, bipedalism was what was available to long-armed hominin ancestors when they walked on the ground, due to anatomical constraints (Stern 1975). There remains no definitive answer to this interesting question.

## Conclusions

Upright striding bipedalism is a specialized form of gait seen, among mammals, only in primates. It reaches its most specialized and obligate form in humans, who use it for efficient terrestrial walking and running. Bipedalism first appeared in the human lineage several million years ago and evolved to its modern form through a number of unique stages. Modern human bipedalism develops during the first 9 years of life, is associated with anatomical (pelvic shape, limb length, large calcaneus and hallux) and mechanical (heel strike, toe-off) specializations, and is characterized by a stiff walking mechanism that exchanges potential and kinetic energy to promote efficiency and a compliant running form. In other primates that use terrestrial bipedalism, walking and running are both compliant and inefficient, there is no hallux toe-off and often no heel strike, and skeletal adaptations like those of humans are lacking. Such gaits in nonhuman primates are used only when they must be, as in gibbons and sifaka who have no quadrupedal gait, or when carrying an object, surveying an area, or displaying.

### Definition

Seasonal outward and return movement of populations between regions where resources and conditions are alternately favorable and unfavorable.

### Introduction

The word *migration* recalls the images of heroic movements of large populations over vast distances. Blackpoll warblers (*Setophaga striata*) during fall migration converge on the Eastern coast of the United States and Canada before embarking on remarkable overwater flights across the Atlantic Ocean to the Caribbean or South America, a nonstop journey of up to 2,400 km or more over the course of 3 days, before reaching wintering grounds in Venezuela or Colombia. Migration here is defined as a seasonal to-and-fro movement of populations between regions where conditions are alternately favorable and unfavorable. Migrating birds can fly great distances, visiting many unique landscapes, and thus face many ecological problems which can be solved either through natural selection shaping innate behavioral programs or through cognitive processes. Although some aspects of migratory behavior are genetically predetermined such as initial departure time, direction, and distance, every migrating bird embarks on a journey that is unique, and therefore exploration, experience, and learning necessarily play a fundamental role in

overcoming the challenges of migration. Migration is a complex behavior that offers a rich study system for evolutionary biologists, as it involves countless morphological and physiological adaptations for efficient movement, behavioral adaptations for optimal use of environmental factors such as winds and sensory cues for orientation, and cognitive adaptations for map learning, long-term memory, and social interaction (Åkesson and Hedenström 2007).

### Performance (Speed and Distance)

The highly physical and energetically costly nature of movement lends itself to optimality analyses. The use of optimality perspectives in analyzing behavioral adaptations and strategies has become an essential aspect of understanding bird migration (Alerstam 2011). If migration is viewed as a conflict between (re-)fueling and movement toward a goal location, then the overall speed of migration can be determined by three variables: the rate of energy accumulation, flight speed, and rate of energy consumption during flight (Åkesson and Hedenström 2007). Fueling between migratory events is an important determinant of migration performance. The rate of fuel accumulation partially determines the overall migration speed. One might, therefore, expect adaptations which maximize both food intake and its conversion into fuel stores, such as fat, which contains the most energy per unit of mass compared to alternatives. Migratory birds are required to locate and ingest food, break it down, absorb it, and create and transport fat bodies to specialized fat deposits. These processes require special adaptations, which among others include flexible organs that grow and shrink in relation to the requirements of fueling and movement. During fueling, migratory birds have been shown to ingest and process food close to their metabolic capacity. To do so, migratory birds grow a larger intestine, gizzard, and liver to boost their food processing capacity, and grow larger flight muscles to lift and transport increasing fuel loads (McWilliams et al. 2004).

Quickly reaching a migratory goal naturally also depends upon flight speed. The sum of the

different power components (parasitic, induced, and profile power, along with the basal metabolic rate), which constrain powered flight, results in a U-shaped curve which relates power (energy consumed per unit time) and speed (Pennycuik 1975). From the power performance curve, two flight speeds of special interest can be calculated: (1) the optimal flight speed for minimizing energy costs ( $V_{mp}$  or minimum power) per unit of time (i.e., to keep flying for as much time as possible on a given energy reserve, irrespective of the distance covered); and (2) the optimal flight speed for minimizing the energy costs per unit of distance covered (i.e., the speed associated with the minimum ratio of power to velocity,  $V_{mr}$  or maximum range) found by drawing a tangent from the origin to the power curve.  $V_{mr}$  allows birds to fly the maximum distance on a given fuel reserve (Pennycuik 1975).

Temperature, air density, and oxygen concentration all decline with increasing altitude, which can have dramatic effects on a bird's flight aerodynamics, respiratory efficiency, and water economy (risk of dehydration). Ascending-descending flight behavior appears to be used for sampling the most favorable winds throughout the air column, and the horizontal wind component is thought to be the most important factor predicting cruising altitude (Bruderer et al. 1995). Migrating birds have been regularly observed flying at altitudes up to 6000 m above ground level (agl), and some migrants such as the bar-headed goose (*Anser indicus*) regularly reach altitudes of 8000 m or more when crossing the Himalayas. When confronted with barriers such as mountain ranges, birds must either make a detour around the barrier or ascend high enough to cross the mountain peaks. Birds which rely on thermal updrafts for migration have been observed at great altitudes, such as the Ruppell's griffon vulture (*Gyps rueppellii*) observed at an altitude of 11,300 m above the Ivory Coast (Braunitzer and Hiebl 1988). High-altitude migratory species are capable of such feats because they possess several types of hemoglobin which operate side by side providing a greater respiratory capacity (oxygen affinity) at high altitudes than closely related lower altitude species. For example, four different

forms of hemoglobin have been discovered in the Ruppell's griffon vulture (Braunitzer and Hiebl 1988).

## Specialization Versus Plasticity

In nearly all bird species, there exists tension between ecological specialization, selecting habitats, foraging sites and food for which they are best adapted, and the ability to respond to unpredictable and novel resources. Ecological plasticity is described as the ability to adaptively respond behaviorally to variable resources in the environment. Plasticity may vary among species, individuals of the same species, and developmentally in an individual. We can assume that the transient period of migration during the annual cycle could provide the greatest challenge for a behavioral profile of dedicated ecological specialization. Stochastic events during migration may play a large role in determining the habitats that migrating birds come to occupy during stopover. Prevailing wind patterns over the Gulf of Mexico can influence the geographic position of arrival following trans-Gulf flight (Gauthreaux et al. 2006). Upon arrival decisions about stopover habitat are more influenced by physiological condition than resource cues (Buler et al. 2007). Habitats and food become more and more dissimilar the further a bird may migrate from their natal area. Stopover sites become critical during migration; the decision where to land is vital for whether sufficient resources can be found and fat reserves restored. In low-quality habitats, birds may have to leave the area completely in search of better stopover sites. Many migrating birds show consistently different habitat use and foraging preferences during the breeding and wintering periods. For example, Worm-eating warblers (*Helmitheros vermivorum*) during the breeding season forage for insects in live foliage. However, during the overwintering period throughout their Central American and Caribbean range worm-eating warblers forage on insects found in dead foliage trapped in the vegetation of the forest understory (Greenberg 1987). Greenberg's (1987) detailed observations and experiments with juveniles

have demonstrated that a complex interaction between innate habitat preference, patterns of substrate exploration, and learning play an important role in developing this seasonal foraging specialization. Similarly, foraging opportunism among *Setophaga* warblers is greatest among conifer-breeding species that winter in tropical areas. In winter, these species occupy broad-leaf habitats, and hence, necessarily employ opportunistic strategies for locating, catching, and handling a diverse array of food types. Exploring novel habitats and monitoring many diverse resources instead of a specialized few would seem likely to require unique cognitive capabilities and/or personality traits. In addition, several studies have found that migrants may use social information to gather information about the quality of habitats. For example, migrants may initially join flocks at stopover sites before foraging on their own and may use resident species as an indicator of high-quality breeding habitats. Such social interactions may support information gathering (Németh and Moore 2007).

### In Flight Decision-Making: When to Deviate from a Direct Path Toward a Migratory Goal

#### Wind and Drift

Decision-making involves determining an action given the available information about relevant environmental features integrated with past experience. One environmental feature, wind, has a very profound influence on the migratory movements of birds. Depending on the direction and strength of the wind, migrants may greatly benefit if the wind flows in the same general direction as the intended course or may be hindered during flight if the wind flows in an opposing direction (Åkesson and Hedenström 2007). In cross winds, a bird may become drifted off its intended course unless it can accurately detect and compensate for displacement. Therefore, selecting favorable winds during migration is important for optimal migration performance if “optimality” is to be achieved (Liechti and Bruderer 1998). The relationship between a migrant’s track, heading, and

**Bird Migrations, Fig. 1** The resultant velocities for three different situations (heading can also be considered air velocity and track can also be considered ground velocity): (a) full-wind drift, (b) partial drift/partial compensation, and (c) full compensation.  $\beta$  = angle between track and wind direction. Note that the body axis of the bird in the figure is aligned with the heading vector

wind direction is shown in Fig. 1. The track (movement with respect to the ground) vector is the additive sum of the heading and wind vectors. An in-flight decision of full or at least partial compensation could be achieved if a bird could perceive lateral displacement from a preferred direction. One way this could be accomplished is by monitoring fixed visual landmarks relative to a bird’s heading (Alerstam and Pettersson 1977; see also Bingman et al. 1982).

Recent studies have demonstrated that migratory birds can choose when to fly to avoid adverse wind conditions and thus improve travel speeds (McLaren et al. 2014). Successful arrival at breeding or wintering grounds depends at least in part on the ability of migrants to make time-sensitive decisions on where to orient to exploit beneficial wind patterns thus maximizing energetic efficiency. However, to expedite travel to their intended goal, migrating birds may initiate migration under nonoptimal wind conditions. During autumn migration in eastern North America, migrants in flight are often drifted laterally by crosswinds but are observed compensating for drift when near the Atlantic coast. The

tendency to compensate for wind drift along the Atlantic coast also increased through the night, while no temporal differences were observed inland. The observed behavior suggests that birds migrate in an adaptive way to conserve energy by *actively assessing* in flight the degree to which they should optimally compensate for wind drift (Horton et al. 2016). Upgrades to the United States national weather radar network to dual-polarization allows a more direct determination of migrant heading (body axis direction) and track (the resultant direction of bird movement, see Fig. 1). However, the effects of drift are difficult to quantify as differential departures of migrants with different preferred directions can occur and lead to a phenomenon known as “pseudodrift” (Evans 1966).

### Barriers

Migrating birds can store large fuel reserves and make nonstop flights of thousands of kilometers. Yet there are many cases where birds refrain from crossing barriers (like open water, deserts, or ice), which are clearly within their flight range capabilities. Why then do birds not always migrate along the most direct and shortest routes to their destinations? Many factors may influence the costs and benefits of alternative migration routes, such as drift, disorientation, predation, stopover conditions and risks of starvation, and weather, most prominently wind. Detours are found among both soaring and flapping flight birds. Large increases in the fuel stores of a bird contribute to higher total body mass, which consequently increases both parasitic and induced drag. Therefore, the relationship between fuel and flight range has a concave function, which means that birds could ultimately save energy if they migrate by short flight steps and low fuel loads rather than departing on longer flights with heavy fuel loads. This optimal fuel load configuration will promote avoidance of barriers and preference for detours if they increase the number of short flight steps travelled (Alerstam 2001). When confronted with migratory barriers or obstacles, a migrant faces a decision regarding seeking out available fuel to cross the barrier in one go, or take an alternative but longer detour around the barrier. The occurrence of directional shifts toward

a coastline during the night suggests that the disposition of migrants to cross large barriers depends in part on physical condition (Bruderer and Liechti 1998). In autumn, migrants approaching the Mediterranean Sea later in the night show a decline in motivation to cross, possibly due to lowering of fuel stores through the night and/or increasing hesitation to cross barriers of unknown extents (Fortin et al. 1999).

### Long-Term Memory

How much are decisions about suitable stopover sites influenced by prior experience? Memory of suitable stopover sites would be a great advantage for optimizing migratory routes and potentially increasing travel speeds. Banding data reveals that experienced adults typically spend a shorter period of time at a particular stopover site than inexperienced juveniles. Many migrants utilize the same stopover or wintering areas year after year (Nolan and Ketterson 1991). Such observations raise the question of whether long-distance migrants have specialized neural capabilities related to long-term memory compared to residents? In one study, migratory Garden warblers (*Sylvia borin*) and resident Sardinian warblers (*Sylvia melanocephala*) were hand-raised and subsequently allowed to explore two unfamiliar rooms during the autumn migratory period. One room contained food while the other did not. The Garden warblers remembered the room with food for at least 12 months, whereas the resident Sardinian warblers demonstrated considerably shorter long-term memory ability (Mettke-Hofmann and Gwinner 2003). Memory and experience may also influence the establishment of new migration patterns. Teitelbaum et al. (2016) demonstrated that experienced migratory whooping cranes (*Grus Americana*) could innovate new migratory routes, which once established, eventually spread to younger individuals via social learning. The presence of older individuals in a group increased the likelihood of occupying new overwintering sites, suggesting that innovative behavior often increases with age because those individuals are more experienced and thus better suited to infer adaptive solutions to novel problems.

## Navigation: Maps and Compasses

An important distinction must be made between three types navigational/homing ability as described by Griffin (1955):

1. *Type 1 or piloting.* To locate a goal by referring to familiar landmarks or landscape features, but may also entail random or systematic searches until familiar landmarks are found. For birds, landmarks are generally thought to be visual, but there is no reason why they would be limited to visual cues. Landmarks in themselves cannot provide compass or directional information, but used in conjunction with compass cues can be used to maintain directionality during oriented flight. Landmarks can also be substituted for compass orientation systems in familiar areas.
2. *Type 2 or compass orientation.* To orient in a specified compass direction without reference to landmarks when released in unfamiliar territory. This may only result in successful navigation if the compass direction leads to a goal or familiar territory. Vector navigation carried out by young birds embarking on their first migration possess inherited information about the direction and distance to population-specific wintering ranges (Berthold and Helbig 1992).
3. *Type 3 or true navigation.* True navigation allows for the determination of a specific direction toward a goal when in unfamiliar territory and in the absence of familiar landmarks or any form of sensory contact with the goal. This is often considered the most complex form of navigational ability, and it is presumed that until goal areas (e.g., breeding or wintering grounds) are established through experience no true navigation can occur.

### Compass Mechanisms

The most remarkable aspect of migration is how birds can routinely return to previous breeding and overwintering sites following migration of often thousands of kilometers. They do so using many sophisticated sensory adaptations and navigation capabilities (Alerstam et al. 2003). The

term *orient* means to determine, relative to some external cue, and keep a compass bearing, while *navigation* refers to moving from a starting location to a specific goal. To accomplish true navigation, birds are thought to use one or several compasses in conjunction with a map (Able 2001). Migratory birds have access to several compass mechanisms for orientation, using information from the sun (both the position and the pattern of skylight polarization), stars, and Earth's magnetic field.

The use of a sun compass by birds was first demonstrated by Kramer (1950). Kramer used mirrors to alter the apparent position of the sun and found that European Starlings (*Sturnus vulgaris*) altered their directional preference accordingly. The avian sun compass is based on the sun's azimuth (the angle of the sun's position projected on the horizon relative to north), with the sun's altitude being irrelevant. Because the sun appears to move across the sky during the day, the use of a sun compass requires calibration by an internal clock (circadian clock). The sun's azimuth at a particular time of day provides the directional information. By experimentally shifting the internal clock of a bird, used in the so-called clock-shift experiments, and recording directional preferences in homing pigeon or migrant orientation cage experiments, the internal clock has been shown to be important for correctly implementing the sun compass. Inexperienced birds must learn to use the sun compass; in homing pigeons, learning appears to take place after the bird is confronted with the need to home, likely spontaneously during extended exercise flights around the home loft. Moore (1987) demonstrated that the position of the setting sun functions as a source of directional information for night-migrating birds. Experimental evidence indicates that several species of migratory birds (but not all; see Wiltschko et al. 2008) are apparently able to perceive polarized light and use it as a cue for orientation. There is also evidence that information from different compass cues can be integrated. For example, researchers have provided experimental evidence that suggests that migratory Savannah Sparrows (*Passerculus sandwichensis*), Swainson's (*Catharus ustulatus*)

and Gray-checked (*C. minimus*) thrushes, and White-throated Sparrows (*Zonotrichia albicollis*) use polarized light cues at sunrise or sunset to calibrate their magnetic compass. The avian visual Wulst of the anterior forebrain and hippocampus may be involved in learning processes supported by the sun-compass in homing pigeons (Bingman and Jones 1994), though the sun compass itself is still operational after Wulst and hippocampal lesions (Bingman et al. 1984).

During the night, when the sun compass is unavailable, migrating birds may rely on information provided by other cues for orientation. In a series of classic experiments, Emlen (1967, 1969) demonstrated that indigo buntings (*Passerina cyanea*) use the stars for orientation during migration. By experimentally manipulating the location and movements of stars and constellations in a planetarium, Emlen (1967) found that buntings derived directional information from the position of constellations relative to each other and to the celestial pole, the point around which stars appear to rotate during the night. Inexperienced juvenile buntings learned the location of north by observing the rotation of constellations around the celestial pole. Star-compass orientation has been demonstrated in several species of nocturnal migrating songbirds, including Bobolinks (*Dolichonyx oryzivorus*), Savannah Sparrows (*P. sandwichensis*), European Robins (*Erithacus rubecula*), and Garden Warblers (*Sylvia borin*). Little is known about specific neural structures involved in stellar orientation other than the obvious assumption that elements of the visual system are involved. Mouritsen et al. (2016) proposed a hypothetical framework for the forebrain organization of both the sun and star celestial compasses.

The Earth's magnetic field also provides compass orientation information for migratory birds. The geomagnetic compass provides migratory birds directional information based on inclination angle and not the polarity of the field (an inclination compass; Wiltschko and Wiltschko 1995). Inclination angle or magnetic dip is the angle of Earth's geomagnetic field relative to gravity or any vertical reference. Along the magnetic equator the Earth's magnetic field runs parallel to the earth's

surface and toward the poles the angle becomes increasingly perpendicular. Observing changes in the orientation preference of European robins (*E. rubecula*) by altering the magnetic field around orientation cages by using Helmholtz coils provided the first evidence of a magnetic compass (Wiltschko 1968). To date, no studies in birds have demonstrated compass orientation derived from either total intensity or polarity of the Earth's magnetic field. Currently, the peripheral transduction mechanism used by migratory birds to gather and process information from Earth's magnetic field is under debate. Magnetic information may be detected by magnetoreceptors in the upper beak and transmitted through the ophthalmic branch of the trigeminal nerve to the brain (Mora et al. 2004). More likely, however, magnetic field direction would be sensed by special photopigments in the eyes (Ritz et al. 2000) and this geomagnetic signal would then be processed in cluster N, a specialized, night-time active forebrain region found in nocturnal migrants. European robins (*E. rubecula*) with lesions of cluster N are unable to orient to magnetic cues but can perform sun compass and star compass orientation behavior.

### Vector Navigation

Juvenile European Starlings have been shown to migrate by orienting toward a preferred direction, but not to a goal. In a classic experiment, Perdeck (1958) demonstrated that juvenile starlings displaced during fall migration from Holland to Switzerland continued southwest along their normal migratory direction ending to reach southern France. Adults, however, could compensate for their geographic displacement and reoriented northwest toward their typical wintering grounds in northern France. Migrating white-crowned sparrows (*Zonotrichia leucophrys*) were similarly displaced longitudinally across North America and only adults, but not juveniles, showed a clear goal (typical wintering area)-directed shift in orientation after displacement (Thorup et al. 2007). The presumably innate direction and distance program of first-time migrants is termed vector navigation, which is not a true navigational mechanism as no cognitive representation of a goal is defined. Only predetermined genetic

information on direction and distance is used. To gauge the distance to fly, many inexperienced migrants have been experimentally demonstrated to rely on an inherited temporal program, which specifies how long they should travel (Berthold 2003) and direction (Helbig 1991). The behavioral mechanisms, which guide inexperienced migratory birds, are a typical example of vector navigation because it is based on a simple determination of direction and distance from a starting location.

### Map-Based Navigation

Map-based navigation denotes a situation in which a bird determines its spatial position relative to a goal based solely on information available at some distant location. Based principally on homing pigeon research, fundamental differences between two theoretical representational types of map are distinguished: a mosaic map and a gradient map. The mosaic map introduced by Papi (1976) is formed from the learned spatial relationships among landscape features (for Papi, those landscape features would be odor patches) and their relative arrangement with respect to a goal. These relationships are presumed to be learned as a bird explores increasingly larger areas of its home range. Although this type of map may be useful over distances ranging perhaps a few hundred kms, for example, some large visual landmarks may be seen at great distance or remote olfactory patches can be coded as being a certain direction from a goal by winds, a mosaic map would be of little use after a displacement far removed from an animal's local experience. Mosaic maps are often considered equivalent to the so-called cognitive maps, but it is unclear whether this is correct. O'Keefe and Nadel (1978) refer to cognitive maps as a mental representation in which spatial relationships among spaces are coded with respect to not only position and direction but also distance. Thus, an animal possessing a cognitive map should be capable of inferring novel shortcuts between any two points on the map. But there is evidence suggesting that homing pigeons are capable of navigating between two such points within their range. Blaser et al. (2013) released food deprived and

satiated pigeons from an unfamiliar site, equidistant between a known food site and home loft. The pigeons knew their geographic position relative to the familiar targets and chose a flight direction reflective of their motivational state.

More discussed as a hypothetical model of map-based navigation relevant at migratory-bird spatial scales are so-called gradient maps (Wallraff 2005), which are thought to be based on at least two gradients of any physical substrate, e.g., atmospheric odors or the earth's magnetic field, which may vary systematically over large spatial scales. Utilizing a bi-coordinate gradient map, birds would learn how navigational cues change in some parameter across their familiar, experienced space. If a gradient parameter varies predictably beyond the familiar experienced space, a displaced bird could obtain an estimate of its position relative to a goal by implementing a neural algorithm comparing remembered values of stimulus at home with the measured values at the displacement site/current location.

### Kramer's Map and Compass Model

Kramer (1953) outlined what came to be called the "map and compass" model of homing pigeon navigation, which in principle would generalize to migratory birds. Kramer's conceptual framework for understanding bird navigation remains the central explanatory paradigm in the field. He described navigation as a two-step process. In the first step, a displaced individual estimates its position in space relative to a goal, such as "I am west of the goal." This step yields the direction to the goal as a bearing. In the second step, a compass mechanism is employed to identify the actual geographic direction of the goal-directed bearing, e.g., "That way is east." The map and compass model has three defining characteristics: (1) a two-component process dependent upon a position-fixing system (map) and an independent compass mechanism; (2) the positioning system computes a bearing toward a goal; and (3) a biological compass is used to identify the direction of this goal-oriented bearing. For homing pigeons, the sun compass identifies the goal direction, and countless clock-shift experiments have been performed as demonstration. Importantly, those

same clock-shift experiments also revealed that the map component remained intact, providing evidence that the position-finding component is independent of the compass component.

Bingman and Cheng (2005) described a hypothetical sequential model of migratory bird navigation which consisted of three phases each supported by three separate, hypothetical map mechanisms. Using a Le Conte's sparrow (*Ammodramus leconteii*) as an example of a nocturnal songbird migrant, a hypothetical spring migration from *wintering* grounds in Florida, USA, to breeding grounds in Saskatchewan, Canada, could be described (Fig. 2). At a global scale, an experienced nocturnal migrant may first use a low-resolution global gradient map, perhaps based on the Earth's magnetic field, to roughly determine its position relative to its goal location in Saskatchewan. A higher spatial resolution but shorter range olfactory gradient map of atmospheric odors could then guide the migrant in areas within a few hundred kilometers from the goal similar to the navigation of homing pigeons. Finally, an even higher spatial resolution but shorter range visual landmark or landscape map, operating within tens of kilometers from the intended goal, may help guide the final approach. The model is designed such that each "map" need only serve to provide enough spatial information to bring the migrant to within the "catchment" area of the next phase map.

## Brain Architecture

Evolution of a sedentary or migratory phenotype, and the associated evolutionary adaptations for coping with or escaping the challenges of highly seasonal environments, are known to correlate with changes in brain organization (Fuchs et al. 2014). Species which migrate longer distances typically have smaller brains than closely related sedentary species. Brain size may be energetically constrained by low food availability, developmentally constrained by short breeding seasons or restricted by bill adaptations, which can limit braincase volume. Small brain size may lead to migratory behavior which compensates for low

behavioral flexibility or vice versa. Although generally larger brain volumes are observed in sedentary compared to long-distance migratory birds, long-distance migrants are observed to possibly have relatively larger dorsal pallial regions (hyperpallium) and hippocampus (Fuchs et al. 2014). The avian pallium tends to be relatively large, comprising ~75% of the telencephalic volume. The question arises as to whether the observed differences in brain organization can be explained by differences in developmental constraints or differences in behavioral adaptations. One possible explanation for smaller brains in long-distance migrants may be a consequence of a restricted developmental window available to juveniles. Comparisons of hatching date and onset of migratory restlessness in stone-chats (*Saxicola* sp.) clearly shows shorter time available for maturation in the longer-distance migrant populations (Helm et al. 2005). These observations may account for differences in overall brain size, but cannot explain the sparing of the hyperpallium and hippocampus from volume reduction in migratory species. One functional explanation is that the hyperpallium is characterized by a visual area, which receives a strong input from the thalamus. A larger hyperpallium may correlate with high visual acuity as observed in mammalian visual cortex. Possible specialized functions such as visual control of the sun-compass and retinal-mediated, geomagnetic sensitivity hosted by the avian hyperpallium could be advantageous in migratory behavior (Bingman and Cheng 2005).

The homology between the avian hippocampal formation and the mammalian hippocampus encourages the hypothesis that the avian hippocampus plays a fundamental role in navigation by migratory birds. The hippocampal formation of migratory species tends to be relatively larger compared to closely related sedentary species (Fuchs et al. 2014). For example, a larger and more microglial dense hippocampal formation was observed in a shorebird species that migrates over a visually complex landscape compared to another shorebird species that migrates over water (Diniz et al. 2016). The growing body of evidence which correlates hippocampus morphology to migratory behavior supports the hypothesis that

**Bird Migrations, Fig. 2** Hypothetical migration map of a Le Conte's sparrow (*Ammodramus leconteii*) using a phase model of global-navigational mechanisms operating at different spatial scales and resolutions. For illustrative

purposes, an experienced nocturnal migrant begins its spring migration at *wintering* grounds in Florida, USA, and journeys to breeding grounds in Saskatchewan, Canada (See Bingman and Cheng 2005)

the hippocampal formation houses some specialized spatial representational mechanism(s), which supports navigation during migration. Notable however, there is little evidence that the hippocampus is necessary for the operation of the sun compass in both homing pigeons and migratory savannah sparrows (*P. sandwichensis*; Bingman et al. 1999). Lesions of the hippocampal formation in homing pigeons results in an impaired ability to use familiar landmarks or landscape features for navigation including the carrying out of corrective re-orientations following displacement (Gagliardo et al. 2001). Based on the homing pigeon data it is reasonable to assume that migratory birds similarly rely on the hippocampal formation when navigating a familiar, local space (See Fig. 2). The sparing (or even relatively larger) of hippocampus size reduction in migratory birds may be at least partially explained by having to hold multiple representations of local spaces (breeding, stop-over, and overwintering sites).

## Conclusions

Migratory birds are confronted with a variety of challenges, each requiring unique physiological, behavioral, and cognitive adaptations. Even mundane problems, such as selection of flight speed, are affected by several factors operating simultaneously. The seemingly routine migration of birds belies its complexity. Migratory birds successfully carry out goal-directed flight of often thousands of kilometers or more over often diverse and unique landscapes. By employing a complex multisensory navigational system, migratory birds overcome challenges encountered such as inclement weather, winds, and migratory obstacles to regularly return year after year to within a few meters of the previous year's breeding or wintering site. Migratory birds exhibit low neophobia, being less hesitant than resident species to enter novel environments, representing a personality trait that may be beneficial when encountering unfamiliar areas during migration. But migrants typically do not invest a lot of time, and consequently energy, exploring unfamiliar environments. Therefore, it is possible

that migrants, which also rely heavily on long-term memory, may be at a disadvantage responding to rapidly changing environments, either climate or human-induced, within a single generation. Social interactions may aid many migratory species, which rely on learning and experience to perhaps rapidly alter their migration patterns when confronted with environmental change. Maintaining a diverse age structure within populations, which include older and experienced migrants, may be critical in adapting to global change (Teitelbaum et al. 2016). To dampen the negative impact of environmental change on migrants, maintaining suitable habitats across the migratory journey is essential. Bird migration remains perhaps one of the most spectacular and mysterious wildlife events.

## Bisexual

Jared Edge  
Oakland University, Rochester, MI, USA

---

## Definition

Romantic or sexual attraction that is directed toward two genders, typically men and women.

---

## Introduction

Bisexuality is a sexual orientation wherein an individual experiences attraction, whether romantic or sexual, that is directed toward two genders. These two genders most commonly refer to male and female, but the existence of other genders in LGBT+ communities can result in individuals expressing attraction to alternate genders. Individuals that identify as bisexual frequently do not experience equal attraction to the two genders,

instead having a preference for one over the other. Bisexuality has been observed in a wide variety of human cultures as well as some animals.

## History

Bisexual individuals have been present in many societies, with a widely varying degree of prevalence and social acceptance. In some cultures, bisexuality is virtually nonexistent, possibly due to intolerance, but in other cultures, bisexual individuals can represent a large portion of the population. In ancient Greece, having sexual intercourse with both men and women was the norm and was even used to solidify student/mentor relationships in a practice known as pederasty (Holmen 2010). Other depictions of bisexual behavior have been recorded throughout history in many cultures. However, the term “bisexual” is a recent construct that was first used in 1892 by Charles Gilbert Chaddock in a translation of Kraft-Ebing’s *Psychopathia Sexualis*, to describe individuals that had sex with both men and women.

Bisexuality was brought to the attention of the scientific community through the work of Alfred Kinsey in the 1940s. Kinsey found that human sexuality could be placed on a continuum, ranging from exclusively heterosexual to exclusively homosexual with varying degrees of bisexuality in between. These findings were used to create the Heterosexual-Homosexual Rating Scale, otherwise known as the Kinsey Scale (Kinsey et al. 1948/1998, 1953/1998). This scale rated individuals from 0, exclusively heterosexual, to 6, exclusively homosexual, with an additional group “X” for individuals that did not report any sexual attraction.

Although Kinsey continued to study sexuality, further research into bisexuality would be sparse until the 1980s when interest spiked, in part due to the AIDS epidemic and the fear that bisexual individuals would spread the disease to heterosexual women. Before the 1970s, bisexuality was believed by many to be nonexistent or even impossible; many researchers simply labeled bisexual individuals as homosexual, and

bisexuality was considered a “lesser form” of homosexuality or was described as “situational homosexuality” (Rodriguez Rust 2002). During the mid- to late-1980s, researchers slowly began to distinguish between gay and bisexual participants. By acknowledging this distinction, research focusing on bisexual individuals became more popular. Despite this increase in interest, bisexual research still lags far behind research on homosexuality.

## Theories

Although Kinsey’s original research suggested a dichotomous model of sexual orientation, this has largely been replaced by a multidimensional model of sexuality. The Klein Sexual Orientation Grid (KSOG) is a commonly used multidimensional measure with 21 scales, representing 7 dimensions of sexual orientation, which participants answer in regard to their past, present, and ideal selves. These dimensions include sexual attraction, sexual behavior, sexual fantasies, emotional preference, sexual lifestyle, and self-identification (Rodriguez Rust 2002). In this model, bisexuality, rather than being the range between heterosexuality and homosexuality, is its own distinct sexual orientation. Many similar scales have been developed in an attempt to properly define what constitutes bisexuality.

In an attempt to better understand bisexuality, researchers have defined several typologies of bisexuality using a variety of different criteria. Taywaditep and Stokes (1998) identified eight types of bisexuality among men based on different combinations of self-identity, sexual fantasies, and history of sexual involvement. Type A and B men were characterized by a high likelihood of being in a committed relationship with another man, but type A men, on average, had fewer male sexual partners than type B men. Type C and D men were characterized by identifying as heterosexual. Types E, F, G, and H all have a bisexual identity. Type E men tended to prefer female partners and reported having had the highest average number of female sexual partners.

Type F men reported having fantasies for men and women equally. Type G and H men both report a high frequency of sexual contact with other men, but few male partners, and type H men reported much higher heterosexual involvement than type G men. This is one example of the many typologies that have been developed to further define bisexuality.

## Prevalence

Early research into bisexuality has suggested that as much as 10% of the population is bisexual, but these findings were based primarily on previous sexual experience, likely inflating this percentage, especially among individuals that were more sexually active. As a number of dimensions that characterize bisexuality have been identified, more recent research has provided more accurate findings. Janus and Janus (1993) reported that 3% of women and 5% of men self-identified as bisexual. Although other estimates have been found, each of these numbers is based on a single dimension, providing estimates from 0.7% up to 14% depending on the dimension that was measured. Despite this difficulty, researchers have determined some patterns, such as bisexuality being more prevalent than exclusive homosexuality when sexual attraction, erotic responsiveness, or sexual behavior is assessed.

Studies that attempt to determine the prevalence of bisexuality have primarily drawn from American populations. As the prevalence of bisexuality widely differs between cultures, obtaining an accurate estimate of the prevalence of bisexuality in humans has been difficult. Some cultures view bisexuality as normal and thus may have a high prevalence, whereas others may condemn it as heinous and actively suppress any individuals that would otherwise identify as bisexual. Additionally, cultures change over time; in many countries, LGBT+ acceptance has been increasing with a poll in the United Kingdom showing that young adults were twice as likely as older individuals to identify as something other than heterosexual (Lawrence 2015).

## Prejudice

As members of the LGBT+ community, bisexual individuals have been the subject of prejudice and discrimination, specifically biphobia. Large portions of the general population, including many members of the LGBT+ community, continue to believe that sexual orientation is dichotomous, with heterosexuality and homosexuality being the only two possibilities. This perception has led to bisexual individuals being seen as “fence-sitters” who have yet to pick which sexual orientation they identify as. This viewpoint has also resulted in bisexual individuals being seen as a social minority in the LGBT+ community, despite being the numerical majority, resulting in biphobia from both heterosexuals and other LGBT+ members (Matsick and Rubin 2018). This misunderstanding has been difficult to disprove as for many, membership in the LGBT+ community is determined by the gender of an individual’s partner. Outside of polygamous relationships, this results in many bisexual individuals being assumed to be homosexual or heterosexual.

Research on biphobia has identified two underlying dimensions: an instability dimension and an intolerance dimension (Brewster and Moradi 2010). The instability dimension is the degree to which bisexuality is viewed as an unstable and illegitimate sexual orientation. This can manifest in beliefs by non-bisexual individuals that bisexual individuals are confused, experimenting, or simply in denial about their sexual identity. The intolerance dimension is the extent to which others are hostile toward bisexuality and bisexual individuals. Among non-bisexual individuals, this can be seen as a belief that bisexual individuals are amoral, sick, and a threat to society. These beliefs are compounded by the misunderstanding that bisexual individuals are more promiscuous than other members of the LGBT+ community.

## Animal Bisexuality

Without the concept of gender, bisexual activity in other species is much easier to define; in this

context, bisexual activity is the act of engaging in both heterosexual and homosexual intercourse. Bisexual behavior has been observed in a wide variety of animals, including primates, such as the bonobo and Japanese macaques; birds, including some gulls and penguins; and some species of fish (Owen 2004). Many of these species will engage in simultaneous bisexuality in which individuals will engage in both heterosexual and homosexual intercourse within a short time span. For the bonobo in particular, nearly all individuals engage in both hetero- and homosexual intercourse, with up to 75% of sexual encounters being non-reproductive. Other species, such as male walruses, will engage in sequential bisexuality in which periods of heterosexual behavior alternate with periods of homosexual behavior (Bagemihl 2000).

Whereas the term “bisexual” typically refers to sexual orientation when applied to humans, it can have a couple of different meanings when used with animal populations. An individual that is described as bisexual possesses characteristics of both male and female sexes. This usually refers to individuals that possess both male and female reproductive organs. This form of the term “bisexual” has been used since the late eighteenth century and is synonymous with “hermaphroditic.” A group that is described as “bisexual” is composed of both male and female members, rather than one that is “unisexual” or composed of only one sex. Both of these uses are largely restricted to biology.

## Conclusion

Bisexual activity can be seen across many cultures and even within other species. However, our understanding of human bisexuality has been complicated by having to account for gender. The inclusion of gender has resulted in a great deal of misunderstanding, both within the scientific community and the general population. These misunderstandings have resulted in biphobia, even from other members of the LGBT+ community. Further research will be required to resolve these issues and to bridge the gap between research with homosexuals and research with bisexuals.

## Definition

Blindsight is the phenomenon where individuals who are completely blind in some or all of their *visual fields* (the total area where objects can be seen as one's eyes are fixed on a single point in space) are capable of detecting, localizing, or identifying a visual stimulus located in their affected visual fields despite denying that they see the stimulus (Cowey 2004).

As the oxymoronic term suggests, blindsight has two components. When presented with a visual stimulus, patients report that they see nothing at all (*blind*) but when questioned about the stimulus (e.g., where it is or what it looks like), they answer correctly more often than not (*sight*).

Blindsight does not occur in all blind patients but in some who sustain damage to the part of the brain that consciously processes and perceives visual stimuli, located in the posterior pole of the occipital lobe (the *primary visual cortex*).

## History

In humans, damage to the primary visual cortex is associated with a complete loss of vision in corresponding parts of the visual field, as demonstrated in the early twentieth century by studying soldiers injured in battle (Holmes 1918). Decades later, it was reported that four patients with

damaged primary visual cortices were not consciously aware of visual stimuli presented to them but, when prompted to respond, moved their eyes towards the location of the stimuli (Poppel et al. 1973). The term blindsight was coined shortly thereafter in a report describing a patient with a surgically removed primary visual cortex (Sanders et al. 1974). Since then, many studies have investigated patients with blindsight using a variety of methods.

## Characteristics

Blindsight exists in two forms (Weiskrantz 1997); the patient either reports being completely unaware of the stimulus (*Type I*) or is aware of the stimulus but does not acknowledge or experience that it is visual in nature (*Type II*).

Besides direct reporting of responses, assessed by presenting a visual stimulus and asking the subject to choose from a set of options characterizing the stimulus (e.g., where it was or what it looked like), several other categories of responses to visual stimuli have been reported in blind humans and nonhuman primates. These indirect measures include hormonal changes, changes in pupillary and blinking reflexes, and the effects of processing of a stimulus in the affected visual field on the processing of stimuli in unaffected parts (Cowey 2004; Stoerig and Cowey 1997).

Patients with blindsight can detect the presence of a visual stimulus and localize it well above the performance expected by chance (i.e., random guessing). However, this ability depends on several factors, including the nature of the stimulus. Generally, subjects perform less well when the shape, orientation, and color of the stimuli is investigated (Cowey 2004).

## Theories

The precise mechanism underlying blindsight is unknown, but several theories have been suggested as potential explanations (Campion et al. 1983) and have been discussed in detail elsewhere (Cowey 2010; Weiskrantz 2009).

These include that blindsight occurs when there is a generalized reduction in normal vision (as opposed to its complete absence) or when some parts of the damaged primary visual cortices or their connections remain intact. In addition, the results of studies on the phenomenon have been attributed to experimental factors such as scattered light from the visual stimulus spilling over into the normal parts of the patient's visual field or *response bias* – the tendency to systematically choose one answer over another when forced to choose between two responses (particularly when the choice is between yes or no).

## Neurobiology

Neuroanatomical changes in the connections between brain areas (within and between cerebral hemispheres) involved in visual processing have been reported in subjects with blindsight (Ajina and Bridge 2016). Intact connections projecting from the retina (through the lateral geniculate nucleus of the thalamus) to other cortical visual areas outside the primary visual cortex are also seen in patients with blindsight. The variability in the integrity of these connections may help explain why some patients with damage to the primary visual cortex exhibit blindsight while others do not (Cowey 2004). There is even evidence that blindsight may be affected by learning, with patients becoming progressively better at detecting stimuli the more they are exposed to them (Stoerig 2006).

The phenomenon has also been associated with functional activation in brain regions associated with the perception of moving visual stimuli (Barbur et al. 1993), although such responses may also arise from the anticipation of the stimulus rather than its actual perception (Cowey 2004).

## Conclusion

Blindsight is a controversial phenomenon, the basis of which is currently poorly understood. Several lines of imaging and behavioral evidence suggest that damage to the primary visual cortex is

associated with residual capacity for visual processing, occurring without conscious perception of the stimuli being processed. The investigation of this counter-intuitive and interesting phenomenon has opened up fascinating questions about the neural basis of consciousness and how stimuli are perceived, as well as about the brain's ability to reorganize and compensate for damage.

## Blocking

Miguel A. Vadillo<sup>1</sup> and Itxaso Barberia<sup>2</sup>

<sup>1</sup>Departamento de Psicología Básica, Universidad Autónoma de Madrid, Madrid, Spain

<sup>2</sup>Department of Cognition, Development and Educational Psychology, Universitat de Barcelona, Barcelona, Spain

## Definition

In the associative learning literature, blocking is typically defined as a deficit in responding to a conditioned stimulus (CS) that has always been paired with an unconditioned stimulus (US) in the presence of another CS previously established as a reliable predictor of the same US.

## Background

Until the late 1960s, it was generally assumed that the mere temporal and spatial contiguity between a CS and a US was a necessary and sufficient condition for conditioning to take place. The discovery of blocking by Leon Kamin (1968) was the first of a series of findings that defied this view, stimulating the development of modern learning theories. His seminal experiments on blocking relied in the experimental design summarized in Table 1. As can be seen, in this experimental design, subjects in both groups experienced the same number of pairings between a light (L) and an electric shock. However, conditioned responding (CR) to the light was significantly stronger in the control group than in the experimental group. In other words, close contiguity between a conditioned and an unconditioned stimulus (L and the shock, in this case) did not suffice to produce strong conditioning.

According to Kamin (1968), this effect reveals that pairings of a CS and a US only give rise to conditioning if the US is unexpected. In the experimental group, when L is paired with the shock, this event produces little or no surprise, because the shock is readily predicted by a previously conditioned white noise (N). This is not the case in the control group, where the shock is completely unanticipated the first time L is presented. The idea that surprise drives learning was soon implemented in formal theories of associative learning. For instance, in the influential model of classical conditioning developed by Rescorla and Wagner (1972), surprise is represented as a prediction error, i.e., as the arithmetic difference between the “expected US” and the “experienced US.” In this model, the amount of learning supported by a conditioning trial is directly proportional to this difference.

Some models developed over the following years attempted to explain blocking by postulating different mechanisms. For instance, according to Mackintosh (1975), blocking can be explained by assuming that attention is biased toward predictive stimuli. In the case of the experimental group in Table 1, when L and N are presented together for the first time, N is the most reliable predictor of the US and subjects will learn to pay more attention to it, leaving few attentional resources to process (and learn about) L. In a radically different vein, Miller and Matzel (1988) proposed that blocking is not due to a deficit in learning itself but to late processes related to the production of the conditioned response. In any case, as shown by these examples, offering a successful account of blocking soon became a touchstone for any theory of associative learning.

Although the blocking effect was initially explored in the area of animal conditioning, during the 1980s, several studies showed that it could also be detected in human predictive learning experiments (Dickinson et al. 1984). This led naturally to the conclusion that the mechanisms underlying different forms of human learning must be similar to the ones responsible for classical and operant conditioning in nonhuman animals. The following

**Blocking, Table 1** Design summary of Kamin’s (1968) blocking experiments

| Group        | Phase 1      | Phase 2      | Test | Result    |
|--------------|--------------|--------------|------|-----------|
| Experimental | 16 N – shock | 8 LN – shock | L?   | Weak CR   |
| Control      | –            | 8 LN – shock | L?   | Strong CR |

Note: N and L refer to a white noise and to the turning on of a house light, respectively; the unconditioned stimulus is a 1-milliampere electric shock; CR refers to conditioned responding

decades of research in human predictive learning were largely driven by the impetus provided by associative learning theories and animal conditioning research.

More recently, it has been suggested that blocking might not be the product of an associative learning process but rather the result of a simple deductive inference (De Houwer et al. 2002). If two conditioned stimuli predict a US, then presenting both of them together should predict and even more intense US. In a blocking design, however, the intensity of the US is exactly the same when only one CS is presented (N) and when two CSs are presented (L and N). Therefore, it can be concluded that one of the CSs (L) is not a predictor of the US. Consistent with this view, blocking seems to be sensitive to participants’ assumptions about the additivity of CSs (i.e., whether two CSs should predict a stronger US or not) or the maximality of the US (i.e., whether the intensity of the US is not changing because it is already happening at its maximal level). Manipulating these assumptions does not only affect blocking in human participants but also in nonhuman animals (Beckers et al. 2006). These findings have raised concerns about the validity of the whole associative learning framework, leading some authors to suggest that blocking and other learning effects are better understood in terms of propositional inference processes (Mitchell et al. 2009; but see Shanks 2010).

## Bob Cook

Matthew Murphy  
Department of Psychology, Coastal Carolina  
University, Conway, SC, USA

Dr. Robert Cook, known to his students, colleagues, and friends as Bob, has studied comparative animal cognition and behavior for more than 30 years, exploring topics such as stimulus control, discrimination learning, and memory. His NIH- and NSF-funded Comparative Cognition Laboratory at Tufts University has been highly successful, both in terms of research productivity that has shaped the field of comparative cognition and as his monumental support and mentorship for student research and education. His lab utilizes touchscreen-equipped, computerized operant chambers to explore comparative visual and auditory cognition in both avian (pigeons and starlings) and human subjects. The Comparative Cognition Laboratory continually funds graduate students and postdoctoral researchers, as well as providing hands-on research opportunities for undergraduate volunteers and outreach programs for local high school students. He is an excellent mentor and has maintained lifelong friendships with many of his former students.

His research has investigated the mechanisms of perception and discrimination, including action categorization (Asen and Cook 2012), motion perception, change detection, the use of time to

sequentially organize behavior (Cook and Rosen 2010), visual and auditory relational concept learning (Cook et al. 2003), equivalence class formation, music perception, pattern and texture discrimination (Cook 1992), and neural substrates of these cognitive mechanisms. Dr. Cook's ultimate goal in research is to explore how birds, as the other major group of visually sophisticated terrestrial vertebrates other than mammals, can form accurate perceptions and representations of the outside world and how they conceptually form relations between real-world objects and events, using a smaller, more compact central nervous system than mammalian brains.

Dr. Cook has authored more than 150 publications, including peer-reviewed empirical articles in high-impact journals, numerous book chapters, and two online multimedia cyberbooks, *Avian Visual Cognition* (Cook 2001) and *Animal Spatial Cognition* (Brown and Cook 2006). Dr. Cook is the publisher of *Comparative Cognition & Behavior Reviews* and has served on the editorial boards of a number of top journals in comparative cognition. He has been active in a number of academic societies, most notably being a founding member and former president of the Comparative Cognition Society. With his personal and engaging style of presenting, Dr. Cook has been regarded as a rock star who does science. He has been active in broadening the visibility of comparative cognition through the Internet and hosting web-based content in comparative cognition for international academic communities and the public, promoting open-access empirical journals hosted in online formats, and offering outreach programs allowing promising high school students to get involved in university-level research. He has also championed the use of computer technology and programming in research, through his classes and research laboratory.

Dr. Cook received his B.S. in Psychology (1976) from Ohio State University and his M.A. (1980) and Ph.D. (1983) in Biopsychology from the University of California, Berkeley, with Dr. Al Riley. He was an NRSA Postdoctoral Fellow (1986) at the University of Texas Health Science Center, Houston, with Dr. Anthony Wright, before taking on a teaching and research position at Tufts

University in Boston in 1986, where he is currently a Professor of Psychology. In addition to his accomplishments in research, Dr. Cook served as Department Chair of the Department of Psychology at Tufts University and as the Dean of the Graduate School of Arts and Sciences.

In his personal life, Bob is married to Sherry, and has two wonderful children, Allison and Matt. Bob is an avid and accomplished guitarist and musician, and he regularly plays with a band of fellow academics. He enjoys swimming and formerly was an Ultimate Frisbee champion in his college days.

## Bottleneck Effect

Pratiti Roy

Department of Genetics and Plant Breeding (Plant Biotechnology), Banaras Hindu University, Varanasi, Uttar Pradesh, India

The term “bottleneck” refers to a point of congestion in a system, drawing an analogy to the constricted neck of a bottle that reduces the flow of a liquid. Population bottlenecks are evolutionary events attributed to the loss of genetic variability over a short period of time. These can occur due to environmental damage, hunting, limited resources, and drastic climatic changes that cause random fluctuations in the

levels of populations. The sudden reduction of population size results in a new gene pool that is not reflective of the diversity and variability of the original gene pool.

Bottleneck effects do not just occur due to a disease that kills a small group of individuals lacking a particular gene, as death due to disease is said to be aided by the process of natural selection. On the contrary, the bottleneck effect results from a sharp decline in the number of individuals in a population due to sudden occurrence of events like natural calamities or human interference, completely independent of selection. The main cause of the decline is anthropogenic activities (e.g., poaching and habitat destruction) as well as natural calamities like flood, famine, drought, earthquake, and even forest fires.

Fisher (1922), Haldane (1927), and Wright (1931) pioneered studies of the bottleneck effect by modeling experiments on evolution and justifying it with mathematical representations. The probability of extinction due to bottlenecks in resource-limited environments has been studied in detail (Wahl et al. 2002) and mathematical models have been elucidated (Levin et al. 2000) taking bacteria as a model organism as massive evolutionary changes are witnessed in them over a single controlled experiment. The concept of extinction probability of genes in the context of this chapter gains more importance than fixation probability as bottleneck effect brings radical changes in allelic frequencies in a population by the overrepresentation of a particular allelic frequency than the other or a complete loss of a particular frequency (Allendorf 1986). Hence, the dynamics of evolution are affected by this effect that renders obstruction to a beneficial

mutation from being fixed (Wahl et al. 2002). Figure 1 presents a visual representation to depict the concept of a bottleneck.

The extinction of the bearded vulture (*Gypaetus barbatus*) from the European Alps in the early 1900s due to extreme hunting is a notable example of a bottleneck effect in the early twentieth century. The drastic decline in population size was a serious cause of concern for the biologists. Pray (2008) had reported that the extirpation of this species from the wild has led the Frankfurt Zoological Society to institute a captive breeding program to revive the vulture populations by reintroduction of captive-bred vultures in the wild which is still in practice. Scientists opined that the lack of genetic variability has led to lack of adaptability among the captive as well as the released birds due to selection pressures caused by environmental dynamism.

Effective population size ( $N_e$ ) is a term denoting the genetic status of a population that reflects the level of genetic variation among populations. This is measured by pedigree data and estimated by DNA-based microsatellite analysis. The data collected from “studbooks” (a type of record of pedigree data for any captive species) as well as that obtained by microsatellite analysis of blood samples of both wild and captive vulture population were much less than that expected by conservation biologists. High  $N_e$  values are required to maintain the evolutionary potential (Gautschi et al. 2003) which if lost, may lead to the complete elimination of the species.

Another example of the bottleneck effect can be clearly seen in the African cheetah (*Acinonyx jubatus*). Population bottlenecks were experienced by the cheetah population around late

### Bottleneck Effect,

**Fig. 1** Sharp lowering of population gene pool due to wiping of a particular type of population demonstrated by the lost green diamonds in the new set of population that survived in Bottleneck Effect

Pleistocene (Raymond and O'Brien 1993) almost leading to their extinction at the end of last ice age. Raymond and O'Brien (1993) conducted genetic diversity analyses of mitochondrial DNA and hypervariable minisatellite DNA on the South African and East African subspecies of cheetah. Female cheetahs mate with multiple males and give birth to a single litter of cubs with different fathers who may be distantly related. The female cheetahs mate with unfamiliar males, and do not repeat mating with males. Thus, genetic variability is maintained via multiple fathers and a single common mother.

Northern island seals are another example of genetic bottlenecks too. This bottleneck resulted from human hunting in the 1890s that left only 20 surviving individuals at the end of nineteenth century (Trupkiewicz et al. 1997). Blood samples from northern elephant seals were collected by Bonnell and Selander (1974) and were examined for protein variations revealing underlying genetic diversity. A lack of polymorphism among the 21 examined proteins supported the lack of genetic variation among the northern island seals, compared with Southern elephant seals, which were not subjected to similar hunting pressures.

The colonial tuco-tuco (*Ctenomys sociabilis*) – threatened subterranean rodent, endemic to a 1000 km<sup>2</sup> area (approximately) in Western Limay Valley and the Patagonian tuco-tuco (*Ctenomys haigi*), the more widely distributed one in the eastern part of the valley and its neighboring areas – show marked differences in social structure, demography, and genetic variation in spite of being in close geographical proximity. These have been widely studied to record genetic variation at cytochrome b gene of mitochondrial DNA. The volcanic eruption of Puyehue-Cordón Caulle in 2011 had marked the reduction in population size and loss of genetic variations in both species, experimentally inferred by the genome level analyses from pre- and post-eruptional reduction datasets (Hsu et al. 2017). This paves the way for the study of bottleneck effects as a determinant to reduce population dynamism.

Humans have also undergone genetic bottlenecks, primarily at the end of Pliocene era, some

two million years ago. Evidence for this comes from variation in human mitochondrial DNA, beta globin, Y chromosomes, HLA alleles, and multiple loci interspersed in the genome including single-nucleotide polymorphisms, microsatellites, and human-specific Alu insertions of both current humans and the Hominid fossil record (Hawks et al. 2000).

Thus, to conclude, bottlenecks in populations create a lack of genetic information due to loss of alleles which has altered the evolutionary trajectories of the aforementioned organisms. Although conservationists try to recover declining populations, the level of deterioration in the genetic variability affects the new gene pool. However, the bottleneck effect is not the only factor in many cases. Related concepts like the founder effect or genetic drift may also play a role.

## Bottom-Up Processing

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

### Synonyms

[Data-driven processing](#); [Local bias](#); [Lower-level representation](#); [Perceptually driven processing](#)

### Definition

In bottom-up processing, an organism's perception of a stimulus relates directly to its perceptual features and does not impose a more abstract structure to the conceptualization of the object (as in top-down processing). Bottom-up processing is thus independent of prior experience

and knowledge. It is thought to represent lower levels of information processing and to focus on detailed stimulus information compared to the more integrated higher-level information that reflects top-down processing (Rauss and Pourtois 2013). For example, when viewing a rectangle, one would see four lines intersecting rather than representing the rectangle as a depiction of a doorway or a window. Although bottom-up processing is thought to be largely automatic (Theeuwes 2010), the same could be said of some forms of top-down processing; therefore, the automatic/consciously controlled distinction cannot distinguish these mechanisms. Rauss and Pourtois (2013) review other common confusions in the literature.

### Bottom-Up Perceptual Processes

More than four decades ago, Kinchla and Wolfe (1979) sought to examine whether visual processing occurred via bottom-up versus top-down mechanisms. They presented subjects with compound stimuli where a global shape (an uppercase letter) was composed of smaller elements (many smaller capital letters), deemed local elements. Bottom-up processes were implicated if subjects responded more quickly when the target letter appeared within the local, versus the global, stimulus (see Fig. 1). The results of those early studies suggested that the form of processing depended upon the size of the stimulus, suggesting that neither process had priority in that particular task. Biederman (1987) famously argued that objects could be recognized by breaking them down into their component parts, such that representations of whole objects were generalized from associations of their featural components. That is, in Biederman's account, bottom-up processing served as the foundation for all top-down processing and was the primary mechanism of object recognition even in adult humans. Although often contrasted with top-down processing, bottom-up processing often operates in concert with these more conceptually driven processes, making them difficult to disentangle (Goldstone and Barsalou 1998).

**Bottom-Up Processing,**

**Fig. 1** If the target letter is E, bottom-up processes would be implicated if choosing the bottom left stimulus the most quickly

**Categorization**

Because bottom-up perceptions are assumed to be uninfluenced by prior experience, they can most easily be studied in infants. French et al. (2004) showed that even for human infants, photographic images of natural stimuli such as cats and dogs can be categorized “solely on the basis of perceived differences in the statistical distributions of the perceptual attributes of the different categories” (p. 383). That is, the categorization of cats and dogs by infants occurs through bottom-up processes, which can be demonstrated by manipulating the relationships of inclusion of perceptual features in the two categories. The mechanism demonstrated for infants in this study is assumed to also underlie categorization judgments in many nonhuman species (Eggermont 2015). During development, human infants typically shift from reliance on bottom-up to top-down processing mechanisms (Quinn and Eimas 1997; Rakison and Oakes 2003). A question of interest for comparative psychologists is whether nonhuman animals also evidence top-down categorization (Fagot and Parron 2012).

Studies of bottom-up processing often make use of artificial categories to exclude the role of experience and learning. It is difficult to control

the role of prior experience with natural categories (Ashby and Ell 2001). However, animals are often studied for their representation of natural categories to better understand the levels of abstraction underlying their representations. If they correctly categorize stimuli as belonging to natural categories such as “animal,” they may do so by attending to observable features such as the presence of eyes and other face-like features and apparent motion rather than by abstracting a general overarching category for all living things (Vonk and Galvan 2014). If they generalize from these observable features to ascertain which stimuli (when responded to) will result in reward, they might be using bottom-up rather than top-down processes. If instead they have generalized a rule such as “choose all images of animals” and recognize that the category “animal” comprises many perceptually unique organisms, such as fish, birds, snakes, and elephants, they may be using a top-down process. Evidence for top-down processes may be determined when animals categorize stimuli, such as worms, as animals despite the lack of obvious features such as faces and limbs. Although many studies have revealed impressive evidence for generalization of seemingly abstract natural categories in species such as pigeons, squirrel monkeys (Roberts and

Mazmanian 1988), black bears, and great apes, the mechanism(s) underlying such performance is nefariously difficult to identify (Vonk and Galvan 2014).

Researchers have also returned to procedures like that originated by Kinchla and Wolfe (1979) to determine whether species like baboons exhibit local or global processing biases. Jitsumori and Matsuzawa (1991) suggested that monkeys attend to global features, whereas pigeons attend to local features when processing stimuli involving human and nonhuman faces and silhouettes. These differences may extend to other bird and primate species as starlings also show a local bias (Qadri and Cook 2015). However, Spinozzi et al. (2006) found a strong local precedence, and local interference of global processing, in capuchin monkeys, suggesting the possibility of a difference between new-world and old-world monkeys in their local/global processing biases. At the same time, Deruelle and Fagot (1998) found significant differences between humans and baboons in perceptual grouping of visual stimuli and also concluded that monkeys do not show the global precedence identified in humans. Attending to local features rather than global constructs may reflect the absence of a symbolic system for labeling exemplars from the same overarching categories that is present in humans. Fagot and Parron (2012) provide a review of several related studies suggesting differences among primates, but importantly, they conclude that top-down processes are also evident in nonhuman primates even though the exact mechanisms underlying perceptual grouping may differ.

Although the term bottom-up has most commonly been applied to processes underlying perception and categorization, more recently, the term has also been invoked to describe a general approach to the study of animal behavior, personality, or cognition. For example, Hopper et al. (2016) describe the utility of a bottom-up versus a top-down approach to studying instances of coprophagy (consuming one's own vomit) in captive primates. In this case, taking a bottom-up approach means to cast aside *a priori* assumptions about how coprophagy fits with other behaviors related to negative welfare assessments and

instead conducting analyses such as principal components to ascertain directly whether it should be included with other "abnormal" behaviors. Using bottom-up approaches allows researchers to let the data "speak for itself" in the sense that generalizations are inferred from specific observations instead of beginning with an assumption of what behavior might look like and testing observations against that model.

## Models of Personality

In research on human personality, a top-down approach would mean attempting to apply a personality structure from another species (often humans) such as the Big Five theory of personality factors onto animal personality. In contrast, a bottom-up approach would involve taking a careful inventory of behaviors specific to the study species and extracting a model of traits that accounts for the variability in such behaviors for that particular species (Vonk and Eaton 2018). Freeman et al. (2013) identified the unique challenges of each approach and developed a method that they argued incorporated both top-down and bottom-up approaches to the study of chimpanzee personality. They pointed to the benefits of a top-down approach in allowing for cross-species comparisons but acknowledged that taking such an approach might lead to poor-fitting models that fail to identify traits unique to the study species.

## Models of Cognition

In the same vein, researchers have recently advocated for a bottom-up approach to studying animal cognition where they eschew the temptation to test whether other species demonstrate evidence of abilities known to exist in humans or other closely related species and instead focus on understanding the mechanisms underlying behaviors demonstrated by the study species (de Waal and Ferrari 2010; Eaton et al. 2018). In comparative cognitive studies, this idea is particularly important as one of the major problems with the field is the anthropocentric bias in which researchers

attempt to seek evidence for human-like cognitive abilities in other species rather than pursuing a better understanding of species-specific cognition. Instead of asking questions like “Does the chimpanzee have a theory of mind?” (Premack and Woodruff 1978), researchers would instead ask: “How does the chimpanzee predict the behaviors of others?” Bottom-up approaches consider the study species to be of interest in their own right, rather than merely by virtue of their comparison to humans.

## Conclusion

Despite being commonly used within psychology, it is clear that the term “bottom-up” has multiple meanings and is sometimes poorly defined (Rauss and Pourtois 2013). In general, it can be thought of as a perceptual process that involves analysis of perceptual features without imposing a more abstract structure or concept onto the stimulus. In addition, it can be applied to strategies that focus on understanding unique cases using direct observation without reference to better known comparisons and without the need to impose a model appropriate for a different species on a lesser-known case.

## Bourgeois Strategy

### Synonyms

[Uncorrelated asymmetry](#)

### Definition

Bourgeois strategy in animal contests is a possible equilibrium solution derived from game theory: escalate when the animal is an owner and retreat when it is an intruder.

### Introduction

Conflicts between animals of the same species usually do not cause serious injury. Before the 1970s, scientists had often explained this by the idea of group selection. That is, if animals fight with full force and are often seriously injured, the survival of the species will face a crisis. However, the idea of group selection is incompatible with Darwinian natural selection, which assumes that

the primary unit of selection is the individual. Maynard Smith and Price (1973) applied game theory to analyze animal contests and succeeded in understanding contest dynamics based on individual selection, not group selection. The most important concept of game theory models is an evolutionarily stable strategy (ESS). An ESS is a strategy that is not invaded by other strategies if most individuals of the population adopt it. Since the publication by Maynard Smith and Price (1973), many contest models based on game theory have been developed. As one such model, Maynard Smith (1982) introduced the bourgeois strategy, where ownership of a resource is always respected during contests. Perhaps this idea fits human intuition. However, it has important logical problems, and researchers have tried to determine whether the bourgeois strategy is evolutionarily stable.

### History of Theoretical Research

Maynard Smith and Parker (1976) constructed a simple model of animal contests named the Hawk-Dove model. This model assumes two behavioral choices during a contest: in Hawk, escalate and continue until injured or until opponent retreats, and in Dove, display and retreat at once if an opponent escalates. In this game, the equilibrium solution is dependent on the value of the contested resource ( $V$ ) and the cost imposed on the loser ( $C$ ). When  $V > C$ , Hawk is an ESS. When  $V < C$ , neither Hawk nor Dove is an ESS. If a player can behave as Hawk with a probability of  $V/C$  and as Dove with a probability of  $1 - V/C$ , it is an ESS. This is called a mixed strategy. Then, Maynard Smith (1982) considered the so-called bourgeois strategy, where an individual plays Hawk when the individual is an owner of the resource, whereas it plays Dove when it is not an owner. It is simply assumed that each individual finds itself to be an owner or an intruder with an equal probability. Individuals can adopt any one of Hawk, Dove, or bourgeois strategies. When  $V > C$ , Hawk is an ESS, whereas when  $V < C$ , bourgeois strategy is the only ESS (Table 1). It should be noted that bourgeois strategy assumes

**Bourgeois Strategy, Table 1** A payoff matrix of the Hawk-Dove-Bourgeois game. Payoffs of individuals in the left column contesting with individuals in the first

row are indicated. Note that even if bourgeois is replaced by anti-bourgeois, the payoff matrix does not change. This table is based on Maynard Smith (1982)

|           | Hawk        | Dove   | Bourgeois    |
|-----------|-------------|--------|--------------|
| Hawk      | $(V - C)/2$ | V      | $3V/4 - C/4$ |
| Dove      | 0           | $V/2$  | $V/4$        |
| Bourgeois | $(V - C)/4$ | $3V/4$ | $V/2$        |

that ownership is not correlated to real fighting abilities (resource-holding power, RHP, Parker 1974) or to the subjective value of the resource (RV). Therefore, it is sometimes said to be an uncorrelated asymmetry hypothesis.

Since both contestants can avoid injury costs, bourgeois strategy is a cheap solution, and thus appears to evolve very easily. However, logical problems arise when one understands that the owner and the intruder are, in mathematical terms, completely arbitrary labels. The owner role and the intruder role can be replaced by any easily perceivable asymmetry so long as each individual can find itself in either of the roles with an equal probability. For example, anti-bourgeois strategy is also an ESS, where an individual plays Dove when the individual is an owner of the resource, whereas it plays Hawk when it is not an owner (Table 1). Maynard Smith (1982) stated that anti-bourgeois strategy leads to an infinite regress where displaced owners go on to displace other owners and that anti-bourgeois strategy is unlikely to evolve when resources provide real value to owners when held for a long time. Mesterton-Gibbons and Sherratt (2014) analyzed, more mathematically, the effect of infinite regress on the evolutionary stability of anti-bourgeois strategy and concluded that infinite regress can facilitate bourgeois-like conventions to some extent.

However, if resources need to be held for a long time, not only the anti-bourgeois but also the bourgeois strategy may not be evolutionarily stable. Grafen (1987) pointed out this problem. The bourgeois strategy tends to provide a positive feedback for owners and a negative feedback for intruders. If an owner wins because it is in an owner role, it tends to be an owner at the next fight and wins again because it retained the

resource in the previous fight. If an intruder loses because it is not in an owner role, it tends to be an intruder at the next fight and loses again because it did not obtain a resource in the previous fight. That is, the premise of the bourgeois strategy that an individual finds itself as an owner or an intruder with an equal probability is very hard to fulfill as long as resources are held for a long time. In this situation, intruders should be “desperados” that do not respect ownership because they lose almost nothing even if they are injured or killed in the fights. Early contest models based on game theory assumed that each contest is an independent event (e.g., Maynard Smith and Price 1973; Maynard Smith and Parker 1976). Clearly, this assumption is not fulfilled when resources are held for a long time. After the publication of the analysis by Grafen (1987), the bourgeois strategy came to be thought of as unreal in nature.

Kokko et al. (2006) breathed new life into the bourgeois strategy by constructing contest models with population-level feedbacks. Earlier contest models consider only two individuals that directly compete over the same resource of a constant value (V), accepting a constant cost of injury (C). Kokko et al. (2006) considered not only the two contestants but also the behavioral dynamics of other individuals in the population. Consequently, V and C are not constant, but dependent on the environment. This model assumes that individuals compete over breeding territories. The background mortality rate of owners and intruders, the probability of lethal injury resulting from losing fights, and the number of territories an intruder can inspect per unit time are set as fixed parameters. The number of intruders per territory, rate at which vacant territories form, etc. are set as feedback parameters (i.e., depend on population strategy). In this model, the bourgeois strategy is an ESS when the mortality

rate of owners is high and fighting is risky. The anti-bourgeois strategy is an ESS when the mortality rate of owners is high and that of intruders is low, the number of territories intruders can inspect per unit time is high, and fight costs are high. The no-respect resolution, where individuals always fight when meeting each other, is an ESS when the mortality rate of intruders is high, that of owners is low, and floaters do not encounter new territories easily. Partial respect for ownership (intruders retreat without a fight with a certain probability) is also an ESS under certain conditions.

### Bourgeois Strategy in Nature

In nature, owners are likely to win contests with intruders in most animals, which is known as effects of prior residence (Kokko et al. 2006). In some animals, it is reported that contests escalated when both contestants regarded themselves as an owner (e.g., Davies 1978; Waage 1988). However, these are not necessarily an evidence of bourgeois strategy. Owners may win contests because competitively superior individuals have been accumulated as owners or because owners place higher RV than intruders and pay more costs for fighting over the resource. It is not easy to distinguish whether owners win because individuals adopt a bourgeois strategy or because of other factors.

Perhaps the most famous example of the bourgeois strategy in the real world was provided by the study of territorial contests in the speckled

wood butterfly, *Pararge aegeria* (Davies 1978). Males of this butterfly occupy a sunspot in woods as a mating station. When another male invades the territory, the owner rushes to him and the two males perform a spiral flight (ascending and descending while flying around each other). Then, one of the males retreats, and the other occupies the territory. In natural conditions, owners always defeat the intruder. To reveal the mechanism that accounts for the owners' dominance, Davies (1978) performed removal-replacement experiments. At first an owner was captured and removed from his territory. When another male came to and occupied the territory, the original owner was released back into the territory. Soon after the original owner returned to the territory, a contest between the two males occurred. In this experiment, the newcomer (the new owner of the territory) always won (Fig. 1). This result appeared to be explained by the bourgeois strategy. In addition, sunspots appear and disappear within a short time as the sun moves. This appeared to fill the requirement of the bourgeois strategy that resources are not held for a long time, and each individual is an owner or an intruder with an equal probability. Moreover, since butterflies do not have organs to attack their opponent such as horns or teeth, it seems reasonable to settle their contests by an arbitrary cue (residency). Davies (1978) had been cited as the empirical support for the bourgeois strategy for decades.

However, later studies did not support the notion that territorial contests of *P. aegeria* are settled by respect for ownership. Wickman and

**Bourgeois Strategy, Fig. 1** The results of Davies (1978): black, an original owner; white, a new owner. This figure is based on Davies (1978) with permission from Elsevier

Wiklund (1983) observed a natural population of *P. aegeria* and found that original owners who had temporarily been out of their territory could defeat a male that was occupying the territory when they returned back. Thus, ownership is not respected. Kemp and Wiklund (2004) reproduced this phenomenon by refined removal-replacement experiments (Fig. 2) and suggested that intrinsically more aggressive individuals are accumulated as territory owners through contests. These results are contrary to those of Davies (1978). Takeuchi and Honda (2009) removed the difference in intrinsic RHP between contestants in removal-replacement experiments using the Japanese hairstreak, *Chrysozephyrus smaragdinus*. In their experiments, original owners always defeated the temporary owner. A possible explanation for the inconsistency between Davies (1978) and the later studies is as follows. In removal-replacement experiments, the original owner is captured and kept until a new comer occupies the territory. Therefore, there is an asymmetry between original owners and new comers: original owners are subjected to captivity stress whereas new comers are not. The level of captivity stress is dependent on the conditions imposed by the experimenter. Therefore, the inconsistencies between Davies (1978) and later studies might reflect the difference in captivity stress. In fact, Kemp and Wiklund (2004) very gently released the original owner.

These results disproved the bourgeois strategy in butterfly contests. However, the question remains of how these weaponless animals settle their contests. Takeuchi et al. (2016) provided a new point of view for understanding butterfly

contests. Interpreting past research based on Lloyd Morgan's Canon, they argued that males of territorial butterflies cannot discriminate the sex of a flying opponent (and have some uncertainty in recognizing the species of flying objects). Consequently, these male butterflies chase each other in the air because they expect their opponent to be a receptive female. The one that judges that the probability of its opponent being a receptive female is sufficiently low quits chasing. It immediately flees from its opponent because its opponent may be a natural enemy. In this framework, butterfly contests are not described as behavioral interactions between two males that try to evict their opponent from the territory. At present, this framework is sufficient to explain competition over mating opportunity in butterflies (Takeuchi 2017).

There is no empirical study providing clearer support of bourgeois strategy than that of Davies (1978). It is sometimes thought to be as an example of bourgeois strategy if an owner defeats an intruder even though the body size of the owner is smaller than that of an intruder. However, the lack of a relationship between larger body size and contest success does not indicate that ownership is used as an arbitrary cue for contest resolution. Ownership and RV are often correlated because owners would have learned the value of the resource. Owners may win because they place higher value on the resource and accept more fighting costs than intruders (Arnott and Elwood 2008). It is very difficult to separate ownership status itself and RV in the real world.

There is practically no reported example of anti-bourgeois strategy so far. In the first place,

**Bourgeois Strategy, Fig. 2** The results of Kemp and Wiklund (2004): black, an original owner; white, a new owner

there are few reports that intruders tend to evict owners. Maynard Smith (1982) cited Burgess's (1976) report on the spider *Oecibus civitas* as potentially supporting an anti-bourgeois strategy. In this species, owners surrender their webs to intruders, leading to a series of displacements. However, there have been no follow-up reports of this behavior in this or other species. In addition, although there are a few examples in which introduced intruders tended to usurp the nest occupied by the owner in the experimental arena (Fernet and Smith 1976; Peeke et al. 1998), these phenomena were not confirmed in nature.

## Conclusion

At present, there are practically no clear examples of bourgeois strategy in the real world. Today, most animal contests are interpreted by one of the following three models: the sequential assessment model (Enquist and Leimar 1983), where contest behavior is regarded as a sampling of the RHP of the opponent, and the individual that evaluates itself as weaker than the opponent retreats; the cumulative assessment model (Payne 1998), where an individual decides to retreat when the accumulated costs from the opponent's and its own behavior reach its threshold; and the energetic war of attrition model (Mesterton-Gibbons et al. 1996), where an individual decides to retreat when the accumulated cost arising from its own behavior reaches its threshold. The bourgeois strategy and its mirror the anti-bourgeois strategy appear to remain possible within purely theoretical studies. Although the bourgeois and anti-bourgeois strategies are both possible on a theoretical basis, owners enjoy considerable advantages over intruders in most fights in the real world. This may indicate that owners defeat intruders not because they use residency as an arbitrary cue for contest settlement but because owners have real advantages over intruders. However, a modern theoretical study suggested that both the bourgeois strategy and the anti-bourgeois strategy can be evolutionarily stable when being an owner increases not only an individual's fitness but also its risk of death

(Kokko et al. 2006). Finding examples of the bourgeois and the anti-bourgeois strategies in nature would itself be valuable.

## Definition

Cognition – the mechanisms by which an individual acquires, processes, stores, and acts upon

information and includes learning, memory, and decision-making.

## Introduction

Cognition refers to the mechanisms by which an individual acquires, processes, stores, and acts upon information and includes learning, memory, and decision-making (Shettleworth 2010). Relatively few basic studies of cognition in cows have been done. Most are framed in an applied setting (e.g., training cows to access automatic feeders, determining food preferences, managing mother-calf separations). These kinds of applied studies can, however, provide a window, albeit limited, into some of the cognitive capacities of cows. But studies of cognition (and other psychological abilities) in cows (and other animals) under more natural conditions generally yield richer and more authentic results. The balance between level of methodological control and context is one that needs to constantly be evaluated when interpreting the scientific literature on cow cognition. It is also important to recognize that the literature on cow emotions, personality, and social complexity also aids in inferring cognitive capacities in these other contexts that can then be more directly tested.

Cow cognition and behavior should be understood in terms of their evolutionary history and adaptations, which include their sensory-perceptual abilities. Modern domestic cows are a genetic mixture of several lineages from as early as over 10,000 years ago, when domestication began. The cow is a diurnal herd animal who depends on all five sensory modalities and who depends heavily on the social group for protection from predators. They are highly vigilant and sensitive to sounds above the highest range of human hearing and therefore often adopt defensive postures and behaviors in the seeming absence of an observable threat.

High reactivity (also labelled nervousness or fearfulness in the comparative personality literature) is an adaptive evolutionary trait in cows. They are facultative “hidiers” in that the young often sequester themselves away from predators

and call to their mother when they are in danger or need to be fed. Mothers usually forage at least 100 m away from their offspring's hiding place and return intermittently to nurse the calf. And lasting bonds are formed between mothers and calves and among herd members.

Therefore, tests of cognitive abilities in cows must take into account the fact that their psychology has been adapted over tens of thousands of years to be exquisitely socially sensitive to conspecifics, closely bonded to offspring and other group members, and wary of strangers.

## Discriminating Objects and Humans

Most studies of cow cognition have probed discrimination abilities, that is, the ability to learn to recognize the difference between two stimuli. Cows are capable of various forms of visual and auditory discrimination learning and retention over days and, in some cases, weeks. They are able to discriminate a wide range of objects based on various dimensions, including geometric shape (Baldwin 1981), color (Gilbert and Arave 1985), size difference (Rehkämper and Görlach 1997), and stimuli differing by both brightness and size (Schaeffer and Sikes 1970).

Cows can also discriminate more complex stimuli than static geometric shapes. For example, calves, as well as adult cows, can easily distinguish between different people based on their previous experiences with them (Hotzel et al. 2005) and can discriminate among individuals who are wearing the same clothes (Taylor and Davis 1998). Some evidence suggests cows can discriminate humans on the basis of facial characteristics but only when they can see the rest of the body, implying that they attend to a number of different features in combination.

## Discriminating Conspecifics

The ability to discriminate among conspecifics forms the basis for social relationships and is an important capacity for a highly social animal

such as the cow. Individual *discrimination* is not equivalent to, but is a prerequisite for, the more complex capacity for true individual *recognition*, defined as a mental representation of an individual's identifying characteristics.

Cows are able to discriminate among conspecifics under a variety of conditions and can also discriminate members of their own species from members of other species (dogs, sheep, horses, and goats). Rigorous controls for the amount of black and white surface, size of head, and other visual aspects of the stimuli ensured that simpler features that distinguish cows from other species could not be used in these studies. These findings suggest a complex capacity for categorization as the subjects were also presented with cows of various breeds and, therefore, various phenotypes and were able to discriminate photographs of different kinds of cow faces from those of other species. That is, cows can categorize the "sameness" of other cow faces despite phenotypic variability as a separate group from the faces of other species (Coulon et al. 2007). Evidence suggests two-dimensional photographs of familiar versus unfamiliar conspecifics are perceived as mental representations of real individuals (Coulon et al. 2009, 2011). These findings suggest cows have a sophisticated visual discrimination capacity when it comes to conspecifics and are also able to mentally create hierarchical categories or, perhaps, a species concept.

## Cognitive Development

One of the broad areas sorely lacking in our understanding of cow cognition is development. Despite evidence of mental representational abilities and, perhaps, basic concept formation in terms of discriminating conspecifics from other species, there is little known about how these capacities emerge or develop over time in cows. And while there are a few studies probing the impacts of various farming practices on calf psychology, there is no robust systematic literature on bovine developmental cognition. One striking area of deficiency in our knowledge of cow cognitive development relates to object permanence.

There are no published studies of object permanence in cows despite the fact that object permanence is a vital cognitive skill that underlies a number of mental representational capacities and its study is critical for interpreting the capacity of cows for higher-order concept formation, as suggested in studies of conspecific discrimination.

One test, the Krushinskii test, which probes how well subjects can follow a moving target, has come closest to resembling a formal test of object permanence in cows. The subjects follow a slow-moving food trolley, eating as they go. When the trolley moves into a tunnel where it cannot be seen (a form of invisible displacement), the subjects move to the far end of the tunnel to await the exit of the trolley, showing they can extrapolate future movements from the past trajectory of the trolley. Cows were capable of successfully completing this task, though they were not as consistent as pigs and goats (Albright et al. 1982).

## Spatial Cognition

Spatial cognition refers to the ability to acquire knowledge of, remember, organize and utilize information about spatial aspects of one's environment, including navigation and learning to discriminate and prioritize the locations of objects and the formation of cognitive maps. Some forms of spatial learning are dependent upon mental representations in both short- and long-term memory and can form the basis of complex cognitive maps of the environment, providing the foundation for many other social and nonsocial strategic behaviors during such tasks as foraging and traveling.

Grazing animals, such as cows, have robust spatial memory abilities, allowing them to forage with optimal efficiency. Hence, they perform well in maze tests. There is a fairly decent body of evidence for this conclusion. In a Hebb-Williams closed-field test of how cows navigate through mazes using detours, they performed favorably compared with pigs, sheep, goats, and dogs (Kilgour 1981). A number of studies of radial and parallel arm maze learning show that cows learn mazes efficiently, can associate several different locations with food, and retain

this knowledge for several hours, days, or even weeks, depending on the test. In a recent study, cows retained a memory of an association between a visual cue (a plastic tub) and a food reward for at least a year (Hirata and Takeno 2014).

Although it is likely that cows use visual cues in these circumstances, other kinds of cues and sensory modalities have not been ruled out.

## Social Learning

One of the ways social species take advantage of group living is through social (observational) learning. Social learning involves observations of a conspecific's behavior and its consequences and the application of that observation to one's own behavior. Some investigators view social learning as a form of deferred imitation or emulation, serving as a mechanism for cultural transmission. But careful experimentation is needed to differentiate among the many theoretical bases for social learning in various species. Nevertheless, the general capability for social learning is one of great significance in the evolution of complex behavior, and cows appear quite capable of learning from observing other cows.

Studies of housing differences in cows provide evidence that, when reared under natural social circumstances, they engage in social learning. For instance, cows who were never afforded the chance to graze began to show normal grazing behavior more quickly when they were grouped with experienced grazers than with inexperienced grazers (Costa et al. 2016). This kind of observational learning seems to be dependent upon having a natural social group to interact with, as cows with very limited contact with conspecifics show fewer propensities to learn from others when given the opportunity.

## Communication

Communication has been defined as "The imparting of information from one organism to another in a way that evokes a detectable response from the recipient at least some of the time"

(Wittenberger 1981, p. 613). Given that communication involves the processing of information, it is an integral part of understanding cognition in any species. There has been limited research on cow communication, and most has focused upon mother-calf calls. There is evidence, however, for individually distinctive vocalizations reflecting emotional states (Hall et al. 1988; Koene 1997). Playback experiments have shown that young calves (3–5 weeks old) are able to discriminate their own mother's vocalization from those of other adult female cows. Auditory cues alone are sufficient. Up until recently it was thought that dairy cows had limited ability to recognize their own calf's vocalizations (Marchant-Forde et al. 2002). However, recent research suggests that cows can recognize and respond to their own calf's vocalizations under conditions where calves are allowed to hide (de la Torre et al. 2016). During the first few weeks of life, calves hide silently in vegetation in order to avoid predation. Hider species tend to have unidirectional communication, but when calves vocalize out of alarm, the mother must retrieve the calf and, therefore, have the ability to recognize her own offspring, thus providing a purpose for bidirectional communication.

People who work with cows report that they respond to human vocalizations. Cows learn to come when called by specific names and are, therefore, capable of learning to associate specific referential information with the distinct vocalizations of another species (i.e., humans).

In general, cow vocalizations themselves appear to carry information about identity, emotional state, and the presence of predators and serve to relate meaningful information to conspecifics. However, much more research, specifically on the use of and processing of vocalizations in cows under more natural circumstances, is necessary to obtain a full understanding of cow communication.

## Cognitive Bias

Cognitive bias, also known as negative and positive judgment bias, is an area of intense interest in

comparative psychology, and the phenomenon is evidence of the complex interaction between emotions and cognition. Likewise, it has important implications for how performance on cognitive tasks is interpreted. Negative judgment bias is sometimes referred to as pessimism and positive judgment bias, optimism. Both involve viewing ambiguous stimuli negatively or positively depending upon prior experience.

There is evidence for negative judgment bias in cows. For instance, young cows are less likely to approach an ambiguous stimulus even 22 h after disbudding (removal of horns with a hot iron) (Neave et al. 2013), and calves are more likely to see an ambiguous stimulus as one previously associated with a negative outcome after being separated from their mothers. These findings show that, much like humans and many other species, when cows are distressed, they exhibit a relatively more negative response bias toward ambiguous stimuli (Daros et al. 2014).

There are no systematic studies of positive bias in cows. Given that a large percentage of cognitive studies on cows are done in contexts that involve either unnatural or negative experiences associated with farming practices, the importance of cognitive bias on the entire cognitive literature for cows cannot be overstated.

## Conclusion

Cows have well-developed discrimination and spatial cognitive abilities and are capable of not only complex learning but feats of long-term memory. They are capable of making discriminations among complex stimuli (humans and conspecifics). They also have social learning abilities and demonstrate cognitive bias. There is evidence for specific meaning in cow vocalizations and learning of referential human sounds. Therefore, there is evidence that cows are capable of forms of learning, cognition, and communication found in many other mammals.

However, in general, the literature on cow cognition is still quite bare, and much more basic research directly probing cow learning and cognitive abilities in a wider range of domains is

needed. For instance, further studies of object permanence would be important as a comparative literature on mental representation with other animals. And other compelling areas in comparative cognition already underway in many other species, including domesticated farmed animals, such as numerosity, learning set, and time perception, beg to be addressed in cows.

[Feeding behavior](#); [Foraging](#)

## Definition

Bovine diet refers to the feeding strategies, type, and amount of food ingested by animals that are part of the subfamily Bovinae.

## Introduction

Bovines are part of the subfamily Bovinae and include the medium- to large-sized ungulates. Bovinae members are herbivores and possess cloven hooves (i.e., split into two toes) and two or four true horns that are not branched. Bovines are also ruminants, which make them well adapted to prairie environments, but they are found across most terrestrial environments. Examples of bovines are the domestic cattle (*Bos taurus*), bison (*Bison bison*), water buffalo (*Bubalus bubalis*), yak (*Bos grunniens*), gaur (*Bos gaurus*), Cape buffalo (*Syncerus caffer*), eland (*Taurotragus*

*oryx*), some species of antelopes (e.g., *Tetracerus quadricornis*), and the nilgai (*Boselaphus tragocamelus*). Most of the knowledge on diet and feeding habits of bovines comes from domestic species, but observation of their wild counterparts has informed the similarities and distinctions. Here we will explore our understanding of what bovines eat, how they digest their food, and their feeding behavior patterns.

## What Do Bovines Eat?

Bovines are herbivores that live in almost every type of terrestrial ecosystem, from the African savannas to the tropical rainforest, to the high mountain areas of Asia. Bovines occupy many feeding niches throughout the world, but mainly they are grazers that feed on graminaceous plants (i.e., grasses, some woody plants including cereals); however some are intermediary grazer/browsers such as the nilgai (*Boselaphus tragocamelus*) and the eland (*Taurotragus oryx*) (Wallington et al. 2007) or are almost exclusively browsers such as the mountain nyala (*Tragelaphus buxtoni*) (Brown 1969).

Bovines will feed on plants of widely divergent physical and chemical compositions, such as lichens, grasses, browse (i.e., forbs/herbs, leaves, and twigs of woody plants), and wild fruits. Many bovines that are preferred grazers will still ingest some level of browse in the wild, such as the wood bison (*Bison bison athabasca*), European bison (*Bison bonasus*), red forest buffalo (*Syncerus caffer nanus*), and anoa (*Bubalus depressicornis*). Similarly, range cattle may also include significant amounts of browse in their diet (Holechek et al. 1982). Bovines will make modifications to their diet throughout the year; during the rainy season, the main diet will consist of grasses, while during dry parts of the year, the diet will contain more browse and other feed sources. This flexibility in diet is used in pasture programs aimed at maintaining botanical species diversity. Also, most bovines require salt in their diets and are known to regularly visit natural salt licks to engage in ingestion of soil, called geophagy, especially in sodium-rich areas (King et al. 2016).

Geophagy may also serve to supplement other mineral intakes, ease gastrointestinal issues, or buffer the effects of dietary toxins (Kreulen 1985).

## Feeding Behavior

### Early Life

Under natural or seminatural conditions, the calf will remain close to the dam during the first few days, but after the 2nd week of life, the calf will begin to interact with other calves in the herd and even begin to graze and ruminate beginning at around 3 weeks of age; several months later, calves will begin to graze regularly with the herd (Reinhardt and Reinhardt 1981). The social interactions of young calves are associated with the learning process of recognition and selection of a suitable diet and habitat, where selection happens through the mimicking of social companions. The progression from maternal care to independence is one of the most sensitive periods for learning among young foragers, making the dam and social peers an important influence on diet selection (Provenza and Balph 1987).

### Social Learning and Social Facilitation

Young ruminants must learn how to select and eat appropriate foods. Two phenomena are especially influential in the development of grazing behavior in young bovines. Social facilitation occurs when the stimulus of another animal eating, approaching, or manipulating feed increases attention toward the feed and subsequently encourages the consumption of feed by others (Galef 1988). A related, but mechanistically different concept, is social learning through the observation of others (Galef and Laland 2005). During both social facilitation and social learning, the mother and young companions serve as sources of information regarding predator detection and the location of food, water, and shelter and, thus, are the most effective social models (Provenza and Balph 1987). These phenomena have been demonstrated in several studies in cattle. For instance, young cattle naïve to grazing have been shown to begin grazing sooner when turned out to pasture with an

experienced social companion compared to when turned out to pasture without a social model (Costa et al. 2016). Calves that were raised in a social group from an early age were quicker to begin consuming solid feed compared to when housed alone (Costa et al. 2015).

Herbivores that feed in large mixed-generation groups, like bovines, will use social learning as a tool to pass on food-selecting information from experienced to inexperienced foragers. Social learning enables an inexperienced animal to avoid the inefficiency and risk of testing each novel feed type, since the strategy of “trial and error” can sometimes lead to the ingestion of highly toxic species (Galef and Laland 2005). Cattle are especially food neophobic, meaning they are reluctant to consume unfamiliar foods (Costa et al. 2014); it is thought to be a mechanism to avoid the consumption of non-nutritive and toxic plants (Provenza and Balph 1987). Food neophobia is known to decrease in the presence of companions and when in familiar environments (Burritt and Provenza 1997). Food neophobia is so prevailing that individuals will even consume familiar foods that previously contained toxins over novel feeds when in an unfamiliar environment (Burritt and Provenza 1997). Through this series of mechanisms and influential social factors, the young bovine learns what and how to eat in its feeding environment and establishes food preferences that last through adulthood.

### Adult Feeding Patterns

In both natural and seminatural conditions, grazing ruminants, including bovines, select their diets from a wide variety of plant species differing in nutritional composition and availability (Provenza and Balph 1987). The selection of and preference for plants to graze, or browse, will depend in part on the individual’s nutritional needs and prior experience with these food sources, as well as the ability to cope with toxins (Provenza 2003).

As gregarious species, the feeding behavior patterns of ruminants typically are performed together as a group in captivity and in the wild (Miller and Wood-Gush 1991). This behavior has

an evolutionary origin offering foraging and anti-predator benefits (Provenza 2003), but even in domesticated ruminants like cattle, this behavior persists. Cattle show crepuscular feeding patterns in which they are most active at sunrise and sunset. Throughout the day, cows will divide their feeding bouts, or visits, into meals; these meals are characterized by a cluster of feeding bouts separated by short time intervals, followed by longer time intervals separating each meal. In confined cattle, different feed bunk designs can impact aggression, feeding time, and access to the feed bunk for subordinate animals (von Keyserlingk and Weary 2010).

Most wild bovine species are also diurnal with crepuscular feeding peak activities, which has been observed in many species, from cattle (*Bos taurus*) to the nilgai (*Boselaphus tragocamelus*) (Oguya and Eltringham 1991). However, these feeding patterns can be altered by the presence of humans or predators. For example, the gaur in India is typically diurnal, but in areas of high human disturbance, they become mainly nocturnal (Duckworth et al. 2016).

### Foraging Strategies

Grazing ruminants typically only remain at a feeding site for as long as the quality and quantity of food remains and will then either search for other food sources themselves (called “producers”) or wait for others to find food and then follow them to the food source (called “scroungers”) (Giraldeau and Caraco 2000). These different foraging tactics are associated with trade-offs: producers can find higher food quality, or availability, at the front or periphery of the herd but risk predation through exposure and limited vigilance during searching and grazing. Alternatively, scrounging is a less risky foraging tactic but, consequently, may limit food quality and availability. Individuals within a herd may also adopt “leader” and “follower” roles in making decisions when to move between feeding locations (Dumont et al. 2005); however, producers of the herd may not necessarily be the leaders. Furthermore, individuals will switch between producing and scrounging depending on the quality and abundance of food sources

and depending on the frequency of individuals adopting each of these foraging tactics in the herd. This is in accordance with optimal foraging theory, which states that an animal will adopt a foraging behavior that brings the most benefits while minimizing costs and thus maximizing fitness (Kie 1999).

### Ruminant Digestive System

Bovines are part of a diverse group of animals known as ruminants, which have a specialized digestive system that allows them to digest large amounts of plant material by breaking down the cellulose fibers through fermentation prior to digestion. A significant feature of the ruminant digestive system is a specialized stomach containing four distinct chambers: the rumen, reticulum, omasum, and abomasum (Czerkawski 1986).

The rumen is the largest of the four compartments, with a capacity of over 200 L, and can be thought of as a large fermentation vat. The rumen and a second compartment, the reticulum, are typically considered one organ because they have similar functions and are separated only by a small muscular fold of tissue. Together they are referred to as the reticulorumen. The reticulorumen contains trillions of microorganisms, including protozoa, bacteria, fungi, and yeast that aid in the fermentation of ingested feed. These microbes ferment and break down plant cell walls into their carbohydrate fractions and produce volatile fatty acids (VFAs), such as acetate (used for fat synthesis), propionate (used for glucose synthesis), and butyrate from these carbohydrates (Grunberg and Constable 2009).

Because vertebrates lack the enzyme cellulase to break down cellulose in plants, ruminants rely on the anaerobic microbial flora of the rumen to digest this cellulose. These microbes function best in a slightly acidic and narrow pH range from 6 to 6.4 (Orskov 1994). Once the animal ingests and swallows forage material, the rumen microflora immediately begins to ferment and break down the plant material. Food is mixed with saliva and moves back and forth between the rumen and the reticulum. The lining of the rumen wall

contains many finger-like projections called papillae that effectively increase the surface area for absorption of volatile fatty acids into the bloodstream for energy production and biosynthesis (Czerkawski 1986).

Following ingestion of large amounts of plant material, ruminants engage in a process called “rumination.” This process involves the formation of a bolus (or clump), of partially digested food which is then regurgitated from the reticulum and re-chewed in order to further break down plant matter. The animal then swallows the bolus and repeats the process. Rumination serves to reduce particle size of plant matter (and thus increase surface area for absorption) and aids in digestion (Welch 1982). During rumination, large amounts of saliva are generated which aids in buffering the pH of the rumen to ensure an optimal environment for the microflora (Carter and Grovum 1990). Rumination occurs predominantly when the animal is resting and not eating, typically consuming about 7–12 h each day (Welch et al. 1970).

The reticulum undergoes a series of biphasic contractions occurring at regular intervals, which serves to separate particles during the passage of digesta between the rumen and reticulum. The first contraction separates the large particles and sends them back to the rumen for further digestion, and sends the finer particles through to the omasum. The second contraction serves to completely empty the reticulum in order to refill with rumen contents and initiates regurgitation of a bolus during rumination (Constable et al. 1990).

The omasum functions to receive digested plant material from the reticulum and absorbs water, minerals, and other nutrients into the bloodstream before the digesta is passed into the abomasum (Prins et al. 1972). The abomasum is the fourth compartment of the ruminant stomach, also called the true stomach, and is equivalent to that of a monogastric stomach with similar anatomy and function. The abomasum serves to further break down digesta through chemical means rather than by mechanical or fermentation methods, like the other compartments. The abomasum produces hydrochloric acid and digestive enzymes such as pepsin that hydrolyze the proteins in the food and pancreatic lipase secreted from the pancreas that

breaks down fat. These secretions help prepare proteins for absorption in the intestines. The abomasum is also equipped with the enzymes which are able to digest the bacteria and other microbes that have passed from the reticulorumen (Stewart et al. 1987). By digesting these microbiota, the ruminant is able to reclaim many of the nutrients (e.g., carbon, phosphorus, and nitrogen) consumed by the microbiota in the rumen.

The unique digestive system of bovines has allowed them to exploit fibrous plant resources, and the absorption of microorganisms in the abomasum provides essential amino acids and B vitamins, which eliminates the need to obtain these elements externally. However, this process comes at a cost: bovines must spend a large amount of time foraging to obtain adequate amounts of feed to undergo gluconeogenesis to extract appropriate nutrients for survival. In fact, the total digestion process for ruminants can take up to 60–80 h from food intake to excretion (Hartnell and Satter 1979).

## Conclusion

In summary, there is a wealth of information about wild and domesticated bovine diets, digestion, and feeding behavior. Bovines are crepuscular grazers that inhabit most terrestrial environments, with some species exhibiting characteristics of browsers. As ruminants, they have the ability to acquire most of their nutrients from forage, but this requires extended bouts of feeding and a specialized digestive system containing microflora to break down the cellulose from plant material. Bovines will learn to graze by observing social models such as the mother and young conspecifics and, as adults, will adopt foraging strategies that allow them to obtain high-quality feed while minimizing predation risk. These characteristics make bovines a unique group of herbivorous ungulates that are common across the globe.

## Introduction

The Bovinae subfamily are within the Bovidae family of the order Artiodactyla and fall under the class Mammalia within the phylum

Chordata and the kingdom Animalia. In the past 20 years, the genetic divergence between species within Bovinae was largely unknown, and characterizations were made on physical differences (Janecek et al. 1996). However, since the early phylogenetic publications, molecular work has characterized differences within the Bovinae subfamily.

Bovinae are characterized as having unique BovB retroposons that identify cattle, nilgais, and spiral-horned antelope as being closely related (Nilsson et al. 2012). Bovinae members are herbivores and possess cloven hooves (i.e., split into two toes) and two or four true horns that are not branched. This subfamily includes ruminant ungulates that have diets comprised largely of grass and have sexually dimorphic characteristics. In fact, all male antelope contained within this subfamily have horns shaped to their particular fighting style for competing for mates (Lundrigan 1996) and larger skulls than females (Brakora 2012). The most common sexually dimorphic characteristic is a difference in physical size.

There are three tribes contained within the Bovinae subfamily: the Boselaphini (four-horned antelopes), Tragelaphini (spiral-horned antelopes), and Bovini (cattle and medium- to large-size herbivores) (Maceachern et al. 2009). Many species of bovines are domesticated or in close contact with humans across the globe, such as domestic cattle, water buffalo, and the yak. Some wild bovines are listed as threatened or endangered such as the banteng (*Bos javanicus*) and the lowland anoa (*Bubalus depressicornis*) or critically endangered and even could be extinct, such as the kouprey (*Bos sauveli*) and the saola (*Pseudoryx nghetinhensis*) (IUCN 2016). Here we will explore the differences between these three tribes of Bovinae, including morphology, reproduction, and some evolutionary aspects that make these animals special.

## Taxonomic Classification

### Boselaphini and Tragelaphini Tribes

The true antelope (Boselaphini tribe) includes the genus *Tetracerus*, the four-horned antelope

(*Tetracerus quadricornis*), and the genus *Boselaphus*, which includes the Asian nilgais (*Boselaphus tragocamelus*) (Nilsson et al. 2012). Tragelaphini is a much larger tribe and contains the genus *Tragelaphus*, comprised of the Bongo (*Tragelaphus eurycerus*), the Greater Kudu (*Tragelaphus strepsiceros*), the Kewel (*Tragelaphus scriptus*), Bushbuck (*Tragelaphus sylvaticus*), the lesser Kudu (*Tragelaphus imberbis*), the mountain nyala (*Tragelaphus buxtoni*), nyala (*Tragelaphus angasii*), and the Sitatunga (*Tragelaphus spekii*) (Matthee and Robinson 1999). The genus *Taurotragus* includes the elands (Matthee and Robinson 1999). These three tribes of antelopes are often used as a source of meat and hide (Maceachern et al. 2009).

**Bovini Tribe**

The Bovini tribe is largely known for its diverse array of species that are widely spread across the world and have many domesticated species that are often used as a source of food and for work. The Bovini tribe contains water buffalo (*Bubalus* sp.), cattle (*Bos taurus*), yaks (*Bos mutus*), and bison (*Bison bison*). Buffalo are divided among two genera, the *Bubalus* and the *Syncerus*, which split from the cattle and bison nearly 5–10 million years ago (Maceachern et al. 2009). The *Bubalus* genus includes the domestic water buffalo (*Bubalus bubalis*), the wild Asian water buffalo (*Bubalus arnee*), lowland anoa (*Bubalus depressicornis*), the Mountain anoa (*Bubalus quarlesi*), and the tamaraw (*Bubalus mindorensis*) (Tanaka et al. 1996). The genus *Syncerus* contains the African buffalo *Syncerus caffer* (Tanaka et al. 1996). The anoa diverged from one another over 2 million years ago, nearly at the same time as the divergence of all *Bubalus* species, and hence is represented as a unique species (Tanaka et al. 1996).

The *Bos* genus contains several species that are domesticated and typically used for farming purposes. The most well-known species include domesticated cattle (*Bos taurus*) and are comprised of two subspecies: the taurine or European cattle (*Bos taurus taurus*) and the humped zebu cattle (*Bos taurus indicus*), which diverged from their common ancestor 610,000–850,000 years ago (Machugh et al. 1997). The *Bos* genus also contains the kouprey (*Bos sauveli*), the banteng (*Bos javanicus*), the gaur (*Bos frontalis* or *Bos gaurus*), the domestic yak (*Bos grunniens*), and the wild yak (*Bos mutus*) (Hassanin and Ropiquet 2004). According to recent molecular phylogeny, the kouprey, gaur, and banteng are closely related, diverging sometime during the Pleo-Pleistocene period, while the yak are more closely related to the American bison (Hassanin and Ropiquet 2004). According to mitochondrial DNA analysis, the American bison (*Bison bison*) is a closer relative to the yak (*Bos mutus*) than it is to the European bison or wisent (*Bos bonasus*), with divergence taking place over a million and a half years ago (Zeyland et al. 2012). A taxonomic summary of the Bovinae subfamily (Table 1) is recreated below and adapted from Maceachern et al. (2009).

**Reproduction and Life History**

**Four-Horned Antelopes**

The four-horned antelope lives in Nepal, subsisting off of shrubs and grasses, and can be seen climbing to reach forage. They are geographically isolated and endangered (Amar et al. 2016). Its vigilance and tendency to hide in thick brush (Krishna Prasad 2015) make it a difficult species to study. It is the only Bovinae that has four horns, which are only present in males and used for

**Bovine Life History, Table 1** Summary of the representatives in the subfamily Bovinae

| Subfamily       | Bovinae                                                   |                                                                    |                                                |                                      |
|-----------------|-----------------------------------------------------------|--------------------------------------------------------------------|------------------------------------------------|--------------------------------------|
| Tribe           | Tragelaphini                                              | Boselaphini                                                        | Bovini                                         |                                      |
| Subtribe        | –                                                         | –                                                                  | Bubalina                                       | Bovina                               |
| Representatives | Spiral-horned antelope ( <i>Tetracerus quadricornis</i> ) | Four-horned antelope and nilgai ( <i>Boselaphus tragocamelus</i> ) | Buffalo ( <i>Bubalus</i> and <i>Syncerus</i> ) | Oxen ( <i>Bos</i> and <i>Bison</i> ) |

competition for mates during the rut. Unlike other Bovinae, they are rarely seen in more than pairs (Krishna Prasad 2015). They are seasonally polyestrous, with mating season occurring June through September, with gestation length being 7.5–8 months (Baskaran et al. 2011). One to two young are produced at birth, weighing 1 kg (Baskaran et al. 2011). They live up to 10 years in the wild (Nowak 1999). There are several species which prey on the four-horned antelope including tigers, wolves, leopards, and small cats (Norwak 1999).

### **Spiral-Horned Antelopes**

The nyala has white stripes and lives in South-eastern Africa. They prefer to graze dense vegetation near woodlands. It is best known for its spiral horns, which are only carried by males. Females reach sexual maturity at 2 years, with a gestation of 7 months (Van Rooyen 1993). Female offspring bond with the mother and stay in the herd, which is usually comprised of females (Tadesse and Kotler 2014). Females weigh 58 kg at maturity, while males weigh 100 kg (Van Rooyen 1993). They live up to 19 years and are preyed upon by lions, hyena, and leopards (Tadesse and Kotler 2014).

### **Water Buffalo**

More than 148 million buffalo are domesticated, with nearly half living in India. The river buffalo and the swamp buffalo are two types of water buffalo that are both considered domesticated, providing milk and meat, and are often used for draft purposes. Though buffalo can be breed year-round, due to temperature pressure and limited rainfall, many buffalo only cycle at certain times of the year and are often considered seasonally polyestrous (Perera 2011). The oestrus cycle is every 21 days, while the gestation period is 315 days on average (Machado et al. 2010). Buffalo bulls reach puberty at 2 years of age but are not considered sexually mature until 30–33 months of age (McCool and Entwistle 1989). Swamp buffalo cows reach puberty around 22–23 months of age (Anjum et al. 2012), while river buffalo can reach puberty earlier at

15–18 months of age (Perera 2011). The natural weaning age of water buffalo is 265 days or 8.8 months (Machado et al. 2010).

Water buffalo weigh 33 kg at birth, with no sex differences (Machado et al. 2010). River buffalo bulls weigh 1000 kg at maturity and females weigh as much as 500 kg at maturity; the swamp bulls weigh 750 kg at maturity, while females weigh as much as 550 kg at maturity. The most striking difference between river buffalo and swamp buffalo is milk production. The river buffalo produce 1000–2000 kg per lactation and are capable of digesting low-nutrient forages (Araujo et al. 2012). The river buffalo is most widely known for its use in production of mozzarella cheese (Araujo et al. 2012). The swamp buffalo, in contrast, produces 430–620 kg of milk per lactation but maintains condition better than the river buffalo (Bonfatti et al. 2012).

### **Domestic Cattle**

Cattle are the most widely distributed and highest population of Bovinae in the world. Cattle are most often used for meat, milk, and draft purposes. The Hindu religion considers cattle to be sacred in Nepal and India; therefore, only the milk is allowed to be consumed.

Cattle cycle every 21 days, are pregnant for 9 months, and are gregarious, with one to two bulls controlling the breeding within the herd, while other mature bulls live together in small groups (Salisbury et al. 1978). Due to the gregarious nature of cattle, a lead cow usually directs the grazing patterns and movement of the herd, and calves inherit the social status of the mother (Reinhardt et al. 1986). Sexual maturity depends largely on whether the cattle are taurine or zebu. Taurine cattle reach puberty around 240–470 days of age, varying largely by breed with lighter breeds such as Hereford reaching puberty sooner than heavier breeds such as Chiana (Laster et al. 1979). Brahman, a breed of zebu cattle, reach puberty much later, averaging 555 days for bulls and 715 days for heifers, though these animals are much more heat tolerant (Fortes et al. 2012). Natural weaning age is

around 8.8 months (Jensen 2009) and mature weight ranges widely by breed.

### Bison

The American bison was recently near extinction, but due to a large rehabilitation program, American bison were recently removed from the endangered list. Bison are not considered domesticated, though it is popular in Canada to raise them for a leaner meat. The American bison is seasonally polyestrous, typically being bred between mid-June and early September in comparison to cattle, who breed year-round (Rutberg 1986). The oestrus cycle is every 21 days, with the cow being receptive for 24–48 h after ovulation, while the gestation period averages 275 days (Love et al. 2017). Sexual maturity for bulls depends on age, averaging  $16.5 \pm 2.5$  months (Helbig et al. 2007). Cows typically give birth to a singleton at 3 years of age but occasionally may have twins. The natural weaning age for bison is 8 months. Forced weaning sooner has detrimental social dynamic effects, as gregarious bison inherit their mother's rank in the herd and associate with the mother for life if weaned naturally (Brookshier and Fairbanks 2003). Bison calves are around 23 kg at birth, while at maturity bulls weigh as much as 1000 kg and cows weigh as much as 500 kg. Life expectancy in the wild averages 15 years but can be as high as 20 years, depending on predation pressure (Lott 2002).

Wolves are the primary threat to bison, and their feeding behavior is modified to reflect predation pressure (Léa and Daniel 2013). For instance, Bison will spend less time foraging and leave more lush vegetation in an open meadow where wolves could be present (Léa and Daniel 2013).

### Conclusion

In summary, Bovinae is an important subfamily containing domesticated ruminants, some of which are critically important for animal agriculture, including use for food and animal labor

across the globe. Bovinae are characterized as having unique BovB retroposons, are herbivores and possess cloven hooves (i.e. split into two toes) and typically have a set of horns. Bovinae comprise three tribes, Boselaphini, Tragelaphini, and Bovini that are very distinct and heterogeneous, from 100 kg solitary forest-living animals to many thousands of herds of 1500 kg savanna-living animals. The adaptability of animals of these tribes to a variety of habitats makes them an important group of ruminants across the globe.

Bovine gaits; Cow locomotion

## Definition

Movement used by the subfamily Bovinae (e.g., buffalo, bison, domestic cattle, yak, and the four-horned and spiral-horned antelopes) to traverse their environment.

Bovinae, a subfamily of Bovidae, consist of buffalo, bison, domestic cattle, yak, and the four-horned and spiral-horned antelopes (MacEachern et al. 2009). The subfamily Bovinae consists of medium to large even-toed ungulates that can be further divided into tribes of *Tragelaphini* or *Strepsocerotini* (spiral-horned antelopes), *Boselaphini* (four-horned antelope), and finally *Bovini* (buffalo and cattle species). Bovinae have a specialized digestive system able to metabolize cellulose. This has resulted in meat, milk, and hide production with strong cultural and financial influence worldwide. The locomotor capabilities within subfamily Bovinae share many similarities although different species within the subfamily vary to a limited extent. For example, domestication of certain bovine species, especially *Bos taurus* (common cattle), has led to altered characteristics including enhanced docility and decreased size (Lenstra and Bradley 1999).

## Major Locomotor Modes

**Bovine locomotion** follows the same general patterns exhibited by most quadrupedal animals, including walking, trotting, and galloping gaits. Furthermore, bovines are also capable of jumping and swimming, but these gaits are situational and less commonly studied (Phillips 2002). Bovinae employ these gaits in the forward direction and adapt their locomotor styles depending on energy capacity and environmental necessity. These locomotor modes are generally classified as either symmetrical or asymmetrical depending on the activity in which they are engaged. During walking and trotting, the forelimbs and hindlimbs exhibit footfall with evenly spaced timing, and this is considered a symmetrical gait. The walking gait pattern most commonly observed in the bovines is the lateral-sequence lateral-couplet (Fig. 1). Meanwhile, during the bovine galloping gait, they have an uneven timing between forelimbs and hindlimbs footfall, and this is classified as an asymmetrical gait (Granatosky 2018).

Dairy cows have been investigated regarding the unusual motions that occur during swing phase (i.e., the portion of the stride where the limb is not in contact with the substrate). Gait analysis reveals that both the forelimbs and hindlimbs of dairy cows are internally rotated and adducted when the limb is first lifted off the ground, nearly contacting the contralateral limb. As the forelimbs and hindlimbs are lifted, the space between the toes, known as the interdigital cleft, becomes closed and then passively reopens at the end of swing phase (Meyer et al. 2007). Dairy cows contact the ground first with their lateral claws and add slight external rotation upon landing. Analysis of the ground reaction forces, the force exerted by the ground on a body in contact with it, during dairy cow locomotion shows that almost all the force exerted at heel strike is distributed to the lateral claw, specifically the outer surface (Meyer et al. 2007; Ossent et al. 1987; van der Tol et al. 2003).

It should be noted that walking behaviors are variable and subject to change depending on the

**Bovine Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in bovines ( $n = \text{four species}$ )

conditions of the walking surface and overall health of the animal (Alsaad et al. 2017a, b). As such, considerable research has been devoted to understanding how substrate influences gait parameters in dairy cows and locomotor health. Poor flooring can affect animal welfare by impairing normal locomotion and thus increasing the risk of lameness (see below) and foot disorders. Pasture is the most comfortable floor for the hooves as it provides the optimal balance of the hoof horn wear and growth and a natural hoof load. Access to pasture is reported to be beneficial in reducing lameness and the risk of cows being affected by hoof disorders compared with zero-grazing herds. Alsaad et al. (2017b) confirmed that pasture results in “optimal locomotor characteristics,” such as duration of gait cycle, longer stance-phase duration, shorter swing-phase duration, higher walking speed, longer stride length, and higher peaks of foot load and toe-off. However, gait variables of cows walking on rubber mats did not show any biomechanical differences compared with asphalt floors; only stride length tended to be longer on rubber mats. Such findings highlight the importance of maintaining proper locomotor conditions for promoting animal health (Alsaad et al. 2017a, b).

Trotting is an alternative gait that is performed at a moderate speed; it is quicker than walking, but slower than a gallop. It is a symmetrical, two-beat gait characterized by diagonally opposite feet moving in phase with each other; for instance, the right hindlimb and left forelimb will be in phase with each other, and conversely the left hindlimb and right forelimb will be in phase with each other. During the trot, bovines will alternate between phases of dual support from either side of the body and phases of suspension, also known as an aerial phase. The trot provides several advantages, namely, that two legs work together in unison to propel the animal forward and provide cushioning from shock (Hildebrand 1989).

Galloping is the fastest method of locomotion utilized by bovines. Specifically, the bovines use a transverse gallop, which is also used by horses and other large, long-legged quadrupeds (Phillips 2002). In this mode, the two forelimbs contact the ground at approximately the same time; the second limb to touch the ground is referred to as the leading forelimb. The leading forelimb remains in contact with the ground for a longer time and helps provide stability. Once the leading limb is lifted off the ground, there is an aerial phase with all the legs off the ground and underneath the animal; this is referred to as the suspension phase or gathered-flight phase (Biancardi and Minetti 2012). Following the suspension phase, the hindlimbs will then contact the ground; the first foot to contact the ground is always contralateral to the leading forelimb and is quickly followed by the neighboring hindfoot. This contralateral relationship between leading forelimb and contralateral hindfoot ensures that the feet do not interfere with one another and disrupt the animal’s gallop (Hildebrand 1959). Finally, it has been determined that the hindlimbs provide a majority of the propulsive forces in the bovine gallop, unlike in other animals where the back is crucial to propulsion (Phillips 2002).

## Lameness

Lameness is an abnormal gait or stance of an animal that is the result of dysfunction of the

locomotor system. This can be caused either by neurological disfunctions or injuries. Lameness is an animal health and welfare concern, as well as a production issue. Pain due to lameness often limits growth because animals may be reluctant to eat or drink. The financial impact of lameness includes losses from decreased production, cost of treatment, prolonged calving interval, and possibly nursing labor. Lameness prevalence ranges from 14.8% in Switzerland to 54.8% in the northeastern United States (Alsaad et al. 2017a, b).

Classification systems are often used to determine the health of cows on farms. They are sometimes referred to as “locomotion scoring methods.” Locomotion scoring methods historically have used a five-level scale by which either farmers, researchers, or veterinarians score up to seven different traits of the cow. Generally, the most important gait abnormalities for detection of

lameness include asymmetric gait, arched back, head bobbing, tracking up, and reluctance to bear weight (Schlageter-Tello et al. 2014). Cows which do not meet the minimum requirements in this scale are deemed as lame (Schlageter-Tello et al. 2015; Fig. 2).

Due to the time-consuming and costly nature of this process, classification is sometimes neglected and cows progress to complete lameness. Automatic lameness detection systems have been developed which continuously detect lameness without manual scoring (Distl and Mair 1993). Another benefit is they can predict the possibility of future lameness of cows. This is done with a camera which records the gait of the cows as they pass through an alleyway. Automatic computer algorithms evaluate hoof locations during the gait. This method has shown a high level of precision and continues to be utilized and improved (Song et al. 2008; van Nuffel et al. 2015).

## **Mildly Lam**

Stands with a flat back, arches when walks. Slightly abnormal gait.

2

## **Moderately Lam**

Stands and walks with arched back. Short strides.

3

## **Lame**

Arched back standing and walking. Favors certain legs.

4

## **Severely Lam**

Constant arched back. Great difficulty moving.

5

## Conclusion

This entry introduces the locomotor behaviors observed in the Bovinae. Overall, the bovines utilize a lateral-sequence lateral-couplet method of ambulation during walking. This is the most common for quadrupeds with longer legs as stability loss is minimal. At higher speeds the bovines use trotting and transverse galloping gaits. The walking gait of cows is commonly assessed and used to identify lameness. Lameness is an abnormal gait or stance of an animal that is the result of dysfunction of the locomotor system. This can be caused either by neurological disfunctions or injuries. Lameness is an animal health and welfare concern, as well as a production issue. Free-ranging cattle on pastures have a lower incidence of lameness.

## Bowerbird Aesthetics and Cognition

Vincent Barnett

Independent Scholar, London, UK

## Synonyms

Bower-birds; *Ptilonorhynchidae*

## Definition

Bowerbirds are a family of passerine (perching) birds from Australia and New Guinea that are renowned for their unique and elaborately colored decorative constructions (or bowers) which are constructed by the males of the species and are used not as nests but as courtship arenas to attract females. The bowerbird family contains 20 different species in five genera (17 species of which construct bowers and the remaining 3 of which do not), and they are found in a range of different habitats such as rainforests and acacia forests.

## Introduction

As has rightly been suggested, bowerbirds became “emblematic of sexual selection ever since [Charles] Darwin’s illustrative use of their mating arenas in *Descent of Man and Selection in Relation to Sex*” (Milam 2010, p. 83). However, the initially more contentious nature of the theory of sexual selection within Darwin’s overall theory of evolution by selection mechanisms meant that the question of whether bowerbirds possessed a refined aesthetic judgment comparable to that possessed by human beings also quickly became a contentious topic. The aesthetic sensibilities of bowerbirds have indeed been periodically recognized in varying degrees in the literature for over a century, but they have also sometimes been doubted.

## History of Bowerbird Analysis

For example, in *The Descent of Man*, Darwin commented that the “playing passages of bowerbirds are tastefully ornamented with gaily-coloured objects; and this shows that they must receive some kind of pleasure from the sight of such things,” this being the “best evidence . . . of a taste for the beautiful” in birds (Darwin 1874 [1871], p. 92, 413). At the end of the nineteenth century, a “strongly marked aesthetic sense in birds” in relation to the functioning of courtship colors was deduced from the construction habits of particular Australian bowerbirds (Poulton 1890, p. 21, 320).

At the beginning of the twentieth century, George Romanes described bowerbird displays as follows: “The most consummate artists in this respect are, however, the bower-birds . . . these sundry cases [of bower construction] alone seem to prove a high degree of the aesthetic sense as occurring among birds” (Romanes 2015 [1910], p. 99–100). Elsewhere he judged that the construction of the bowers furnished “the most un-exceptionable evidence of true aesthetic, if not artistic feeling on the part of the bird which constructs them” (Romanes 1898, p. 279).

Bowerbirds actively painting or plastering the walls of their bowers with colored materials were first observed in 1920 (Marshall 1954, p. 51), further cementing the idea that these birds possessed a refined aesthetic sense. It was judged by one naturalist of the era that: “The ‘Bowers’ of the ‘Bower-builders’ are the most remarkable variants on ‘Secondary Sexual Characters’ yet brought to light” (Pycraft 1913, p. 158, Plate 29). Some early scholars even explored the link between bowerbird decoration, what was termed pre-aesthetics, and the initial origin of art itself (Soderberg 1929).

By the mid-twentieth century however, it was declared: “The fact that some bower-birds select objects that appeal to man’s sense of beauty is no proof that such articles have a similar effect on the bird,” and on a separate topic: “There is no evidence whatever that they are more intelligent than any other crow-like bird” (Marshall 1954, p. 185, 67). The idea that one central motivation for bower construction was primarily an aesthetic one was

correspondingly doubted in the literature of the period as an “anthropomorphic generalization” that was unsupported by any experimental evidence (Marshall 1954, p. 1). Instead, the bowers were conceived at this time more as a displacement nest-building activity with more conventionally avian reproductive and territorial functions (Milam 2010, p. 92), and bower painting activity was seen as straightforward courtship-related feeding behavior.

However, more recently the pendulum has swung back in the other direction, and it has been concluded that bowerbirds should be regarded as true artists with sophisticated aesthetic sensibilities and relatively high intelligence, with the bowers being both artistic and reproductive-related outputs (Attenborough 2007; Endler 2012, p. 282). This conclusion is reached partly from the techniques that are sometimes employed. For example, some bowerbirds construct forced perspective illusions for their bowers in order to manipulate the perceptions of the females. Objects are arranged on the floor leading up to the bower so that they increase in size as the spacing from the bower increases, creating a type of artificial perspective or optical illusion, this being a basic technique of human artistic composition since the Renaissance (Costandi 2012). Other bowerbirds use color constructions to influence the female’s perception of elements within the bower. The nature of bowerbird art and aesthetics and its underlying cognitive foundations will, consequently, be the main focus of the rest of this entry.

## Bowerbird Aesthetics

Art can be defined as the corpus of animal activities devoted to creating visual, aural, language-based, and/or performance-related artifacts and processes that express an individual’s (or a group’s) imaginative ideas, concepts, and/or skills and techniques; these artifacts have been designed to be consumed by an audience for their aesthetic beauty, emotional engagement, and/or intellectual stimulation (Barnett 2019). How do bowers as artifacts meet various aspects of this definition?

Bower constructions can be divided into three main types: court bowers (ground objects on a prepared open clearing), avenue bowers (objects within constructed walls made from sticks), and maypole bowers (objects within sticks around a sapling or small tree, sometimes with a roof). Variants on these also exist such as double-maypole bowers and hut-maypole bowers (Prum 2017, p. 184). The males decorate their bowers with various objects of particular selected colors: for example, satin bowerbirds prefer blue objects while spotted bowerbirds prefer green objects (Kelley 2017). These favored colorings are often tailored to species-specific female preferences. Archbold's bowerbird prefers certain ornate feathers from a particular bird of paradise for their bower decoration, these feathers being particularly difficult to find (Ridley 1993, p. 143). In addition, it has been suggested that "geographically varying bower styles may be a culturally transmitted trait, like human art styles" (Diamond 1986), although sexual selection may also play an important role in initially developing bower types (Albert et al. 2000).

The individual collected objects used for constructing and decorating the bowers include both a large variety of naturally found objects such as twigs, leaves, pieces of bark and bamboo, flowers, stones, small pieces of rock and charcoal, fungi, moss, seeds, fruits and fruit pulp, berries, shells, feathers, straw, amber, and even dead animal parts such as snakeskin, insect casings, fossils, and animal bones. Also, some man-made objects made from glass, metal, cloth, and plastic are used where they are available such as pieces of broken glass, plastic bottle tops, pieces of fabric, pins, and even clothes pegs. These found objects are carefully arranged either individually or in groups of objects, the groups being either flat or made into deliberately constructed and shaped piles, usually with appropriate color coordinations.

It has been suggested that species select their favored colors in relation to the regional light regime in which they reside. Bowerbirds in foggy ridge tops with limited visibility select black decorations whereas those in sunlit locations select bright colors (Borgia 2002, p. 1052). One observer of bowerbirds described the

operation of their evaluative judgment regarding the collected items as follows: "He found that the males are very selective about the objects they choose. They put a flower into the wall of moss they have erected, stand back, and look it over. It frequently happens that they remove it and place it elsewhere" (Eibl-Eibesfeldt 1975, p. 144). It has therefore been concluded that bowerbirds possess "an extraordinarily broad aesthetic palette" for colors, materials, and for intricate designs (Prum 2017, p. 193).

Although some bower constructions are fairly simple in composition, some others are very complex and extensive in scale and take weeks to construct, using as many as 1000 short sticks, reaching heights of up to 1.5 m and widths of up to 2.5 m; some of the outer constructions are so well-made that they are waterproof (Gould and Gould 1997, p. 204). Many of the bowers are also aesthetically pleasing even to the human eye – one bower is made in a decorated Christmas tree style – suggesting that aspects of aesthetic appreciation are common to different animal species. For example, some bowerbirds that collect blue-colored objects for their bowers collect various shades of blue objects and then arrange them in a blue-shading mosaic pattern. Other bowerbirds paint the internal walls of their bowers with various colored substances such as masticated plant matter or berry juice (Bravery et al. 2006). The bowers of many bowerbirds are continually repaired and reconstructed as is required in relation to instances of climatic, animal, or marauding competitor interference.

Finally, some of the avenues that are constructed by bowerbirds for their avenue bowers are very skillfully and carefully crafted from large groups of branches to create shaped and defined internal spaces such as ovals, triangles, or semicircles and also utilize varieties of roofing structures, indicating an understanding of the principles of architectural design, in addition to the principles of color coordination. Given this very extensive range of constructed aesthetic features and judgments, to deny that bowerbirds are indeed avian artists and architects would be highly ungenerous.

## Bowerbird Cognition

A central issue arising from bowerbirds being defined as avian artists is: what are the cognitive foundations of their various sophisticated aesthetic and architectural understandings? Various investigations into this topic have yielded some noteworthy results. For example, one recent study concluded on this issue that even accepting that “birds possess relatively large brains for their body sizes” (Gibson 1990, p. 111):

Birds building bowers have relatively larger brains than both related and unrelated species that do not build bowers. Within the bowerbird family, species that build more complex bowers possess correspondingly relatively larger brains. This is seen separately in both avenue builders and maypole builders, as well as across the family as a whole . . . although the relationship between brain size and bower complexity (a sexually selected trait) is stronger in male bowerbirds, the same trend is also seen in females. (Madden 2001, p. 836)

In other studies, a significant relationship between bower complexity and cerebellum size, rather than overall brain size, was detected, and the fact that bowerbirds had larger whole brains and telencephalon minus hippocampus regions than non-bower-building catbirds (a variety of songbird that are ancestral to bowerbirds) was also recorded (Borgia 2002, p. 1052; Day et al. 2005; Rowland 2008, p. 22). The cerebellum is usually cited as the location of implicit and procedural learning and motor skill abilities, these being key abilities used in artistic training (Molinari 2002). It has correspondingly been indicated that some bowerbirds develop and improve their bower-construction skills over time, suggesting that there is an important learnt component to bowerbird artistry (Kelley 2017).

In terms of examples of particular bowerbirds, it has been reported that the “average brain size of males of the complex bower builder *C. lauterbachii* [the yellow-breasted bowerbird or Lauterbach’s bowerbird] was 80.6% larger than that of the male catbird *A. melanotis*” (Madden 2001, pp. 835–836). The yellow-breasted bowerbird (which is around 270 mm in size and found in the grasslands of New Guinea) constructs a complex avenue-type bower with various walls made

of sticks and grass built on top of a platform made also of grass and sticks. In a departure from the standard form of avenue bower construction, the yellow-breasted bowerbird builds two parallel walls with a central avenue (as is standard), but then it also includes two additional wall constructions, one at each end of the bower, of similar size and composition to the two central walls, producing an elongated “H”-shaped enclosed space. Another unique feature of this bower is that the two central wall constructions slope outwards. The entire construction can weigh up to five kilograms (Rowland 2008, p. 121, 24; Marshall 1954, p. 4).

The bower is then decorated in the usual manner with berries, stones, fruits, clay, and so on of particular favored colors (blue, green, gray), and the walls are painted, as is the case with other bowerbird species. As has been outlined:

[This] bower architecture is of singular interest . . . The Yellow-breasted bird . . . has added an extra wall of sticks and an avenue at each end . . . In the two additional avenues it forms its own characteristic end-display and, in addition, still decorates the original central avenue and sometimes inserts ornaments among the sticks of the walls . . . [the natural history collector F.S.] Mayer believes that the older birds become “master builders” and says that their terminal avenues come to resemble “two sweeping parallel roadways.” (Marshall 1954, p. 108)

The contrast between bowers built by younger and older yellow-breasted bowerbirds is sometimes very stark, particularly with respect to the end-displays. It can plausibly be suggested that this additional bower complexity is linked to this particular bowerbird’s heightened brain capacity (which is expressed both as inherited instincts and as the capacity for learning) compared to similar non-bower-building birds such as catbirds.

As has been concluded on a related issue, “those avian species that have relatively large brains, such as corvids and parrots, also display cognitive abilities that have hitherto only been demonstrated in large-brained mammals” (Horik et al. 2012, p. 82). Although the link between brain size and intelligence is not automatic and direct across all species, whale brains are much larger than human brains, but whale neocortex is less complex than human neocortex (Fields 2008), the fact that the comparative literature on

bowerbirds compares them very appropriately to ancestral catbirds is reassuring on this issue.

## Avian Aesthetics and Cognition

While no other bird families and species construct large external artistic displays like the 17 bowerbird species, other bird species do behave and respond aesthetically in various significant ways, for example in the process of choosing mates, constructing nests, and by means of birdsong and other vocalizations. For example:

The Great crested flycatcher, *Myiarchus crinitus*, usually adds a shed snake-skin to the lining of its nest. Tree swallows, *Tachycineta bicolor*, go to apparent great lengths to gather specifically large white plume-like feathers for that purpose, and the Red-eyed vireo, *Vireo olivaceus*, adds the paper from hornet nests to the *outside* of its nest. (Henrich 2013, p. 745)

Most famously, the peacock's tail is one of the most artistically extravagant examples of body adornment in the animal world. It was initially troubling for Darwin to a significant extent as it could not possibly have evolved by natural selection, as it is functionally a "waste" of resources. He resolved the issue by developing the concept of sexual selection to explain its evolution.

The development of visually extravagant body decorations requires the parallel evolution of associated cognitive abilities in order to fully appreciate them. The fact that human beings also find the peacock's tail to be beautiful suggests again that there is a definite overlap between human and animal aesthetic understanding, it being suggested as early as the beginning of the nineteenth century that "the idea of beauty of person, is synonymous with that of health and perfect organization" (Prichard 1813, p. 41). The most well-known extravagantly decorated birds are the birds of paradise (Paradisaeidae), 42 species in 15 genera, which are known for the elaborately developed and brightly and brilliantly colored plumage of the male birds. Birds of paradise do not construct bowers but they do use display arenas for mating purposes.

In addition to bodily adornments, a key element of avian cognition has evolved in relation to the development of birdsong, which is species-specific and which is developed through a combination of instinct and learning that is very precisely tuned in different ways for each different species (Trivers 1985, p. 103). It is governed by particular interconnected regions of the avian brain designated as the song system. As Darwin outlined, birdsong functions both to attract the attention of females and as a form of competition (Darwin 1874 [1871], p. 369); vocalizations can also act as indications of territorial control and as a form of defense. For example, as well as producing birdsong, various bowerbird species are very good mimics and they can reproduce a wide range of both natural and artificial sounds when required, such vocal mimicry aiding against some predator attacks.

The complexity of some birdsong is revealed by the fact that: "Both mating partners of the African bird *Trachyphonus d'arnaudii* sing a melody in duet, in which each takes a turn and sings only certain parts. They harmonize so well that a listener has great difficulty in discerning two birds instead of one" (Eibl-Eibesfeldt 1975, p. 147). This indicates that some birds not only sing mechanically but can listen to another example of birdsong and carefully synchronize with it, indicating the presence of a form of active musical intelligence. Finally, the fact that some species of birds show "community song patterns" that can vary by region and improve aesthetically through practice suggests that something akin to birdsong culture may exist among some bird species (Thorpe 1963, p. 419, 425), and this is also indicated by some other bowerbird behaviors (Hopper and Whiten 2012, p. 463).

## Conclusion

Bowerbirds understood as avian artists who utilize an avian variant of the hypothesized "art instinct" demonstrating skill and virtuosity (Dutton 2009, p. 53) clearly illustrates that avian cognition can be highly sophisticated and is tailored to specific behavioral functions. In terms of

explaining why bowerbirds build bowers, the main theory that has been proposed in the literature is that they provide a physical protection for the females against forced copulation by the males as they display (Borgia 2002, p. 1051).

This may very well be correct as part of the solution but it cannot be a complete explanation, as the bower-adorned decorations do not serve this function, only the bower structures themselves do. Therefore to explain the sophisticated decorations, aesthetic factors may have to be included: the female may select the bower that serves as the best protection *and* is the most beautiful to behold as an expression of the particular individual that created it (Henrich 2013, p. 750), the latter choice helping to ensure that the bird's offspring will also have a highly developed aesthetic sense.

While only bowerbirds construct physical art objects, many other birds use aesthetic judgments and behaviors such as birdsong and selective mating choice. In relation to the basic concepts of evolutionary psychology, it has been suggested on the topic of brain modularity and birdsong that: "Birdsong learning shows other characteristics of modularization in that it is domain specific, is based on a localized and highly structured neural system and exhibits a level of innate specification" (Searcy and Nowicki 2019), very similar to the functional neural networks of biological modularity (Barrett 2015, p. 45). However, as is usually the case with various types of animal behavior, birdsong is a combination of innate and learnt functioning that is tailored to the individual species and specific behavioral focus under consideration.

produce in an attempt to woo females. Of the 20 species within this family, found only in Australia and New Guinea, all are polygynous (males mate with more than one female) apart from three monogamous species of catbird. In the polygynous species, males construct some form of bower or display arena as part of their sexual display, and each species decorates these display areas using objects according to their own specific color palette (Fig. 1). Females prefer to mate with males that have well-constructed, highly decorated bowers (Borgia 1985; Madden 2003), and mating takes place either in or near the bower. It is a common misconception that bowers are nests, but they exist solely to persuade a visiting female to mate with the owner.

## Courtship

The polygynous bowerbirds provide no parental care or resources to the female. Once a female has copulated with a male, she builds a nest and raises her offspring alone. This mating system results in skewed mating success by males, where a handful of high-quality males gain the majority of copulations (Borgia 1985; Madden 2003; Kelley and Endler 2012a). Bowders are therefore of great

## Bowerbirds

Laura A. Kelley  
Centre for Ecology and Conservation, University  
of Exeter, Penryn, Cornwall, UK

## Introduction

Bowerbirds, family Ptilonorhynchidae, are renowned for the extravagant displays that males

importance to the males, as they must help to persuade a female that the owner is the best male to father her offspring. To do this, males produce an extravagant multicomponent, multisensory courtship display. Not only can the female assess the male's bower and decorations; he also dances around the bower, produces vocalizations, and may also include other species-specific courtship components.

## Bower Types

Each species of bowerbird builds a specific type of bower, which can vary in complexity from a simple cleared area of ground covered with green leaves created by the tooth-billed bowerbird (*Scenopoeetes dentirostris*) to the large hut bower created by the Vogelkop bowerbird (*Amblyornis inornatus*). Bower styles can be classified into three main types: court, avenue, and maypole (Frith and Frith 2004). The most well-studied species of bowerbird are the satin (*Ptilonorhynchus violaceus*), spotted (*P. maculatus*) and great (*P. nuchalis*) bowerbirds that build avenue bowers, and the Vogelkop bowerbird that builds a maypole bower. Males tend to have traditional sites for bower location, where the same male will rebuild his bower each year at a location within that site. The specific location can vary due to variation in vegetation cover and therefore the lighting conditions of the display area (Miles and Madden 2002).

It can take a male up to 7 years to learn how to build a bower and to acquire a territory. Immature males may spend time at the bower of a mature male, where they will help him maintain the bower and gather decorations. However, once a female turns up, the resident mature male chases off any immature males in the area. Although the dynamics of bower inheritance are not clear, it seems that when a bower-owning male dies, his bower site is taken over by one of the immature males that have assisted at the bower. Until this time, immature males of species including spotted and great bowerbirds also build practice bowers that are poor attempts at bower construction. They often congregate at these bowers in groups to practice their courtship displays.

## Bower Decorations

Males of each species decorate their bowers with both natural and man-made objects restricted to a specific color palette. Satin bowerbirds collect blue objects, for example, spotted bowerbirds prefer green, and Vogelkop bowerbirds use red and blue. The tooth-billed bowerbird decorates his courtship arena with green leaves turned a particular way up (Frith and Frith 2004). The decorations used on each bower can also vary across populations within a species (Uy and Borgia 2000; Madden 2006; Haruyama et al. 2013). Local object availability likely plays a role, as bowers located near populated areas have higher numbers of man-made, and therefore brightly colored, objects on their bowers compared with more rural bowers.

The number and/or types of colored decorations a male displays on his bower are of interest to females, and females prefer to mate with males that have more highly decorated bowers in most species studied to date (Borgia 1985; Madden 2003). The specific decorations that best predict mating success in spotted bowerbirds (and perhaps other species) appear to vary across populations (Madden 2006). Furthermore, decorations are not always the most important aspect of female choice; in great bowerbirds, females do not appear to choose males based on decoration number or type (Kelley and Endler 2012a). Decorations are one component of the male's display, and there are other display components that a female can use to assess the quality of a male. Females may therefore vary on which aspects of display they use during mate assessment, or they may take into account several aspects of the male's display before making their choice.

In species where decorations are an indicator of male quality, the number of decorations that a male can display appears to be under social control. In spotted bowerbirds, when the number of decorations a male had on his bower was artificially increased, stealing and destruction rates from rivals increased until each male eventually returned to the number of objects similar to that originally displayed (Madden 2002). Similarly, when satin bowerbirds were all given the same

number of decorations, males that had more decorations prior to standardization had more decorations at the end of the experiment, because they were better at defending them (Wojcieszek et al. 2007). It therefore seems that in these species, males can defend a certain number of decorations against theft, which may form the basis of an honest signal of male quality that is available to females during mate choice.

What might this honest signal be? Surprisingly, the objects that males preferentially display on their bowers are not particularly costly to locate and do not degrade faster than less preferred decorations (Madden and Balmford 2004). There is likely be some small cost in acquiring decorations though, as males often reuse decorations from the previous year, moving them across to their new bower site (Doerr 2009). Males also do not preferentially display more costly decorations to the female during courtship. The physical display produced by the males may be important in holding the female's attention: in great bowerbirds, males display primarily red and green objects to the female as well as red/brown sticks. The diversity of colors and the frequency of switching to different colors affect how long females stay in the bower watching the male and assessing his display (Endler et al. 2014). The longer a female stays in the bower, the more likely she is to mate. Females may therefore not be assessing males purely on the number of types of decorations they have on their bower but also what he does with those decorations during courtship displays.

### Other Components of Courtship Displays

Alongside using colored decorations on their bowers, great bowerbirds create an extra few tricks for viewing females. Males of this species arrange white and gray stones, shells, and bones over their display courts in order of size. The smallest objects are close to the bower entrance, and they gradually increase in size as distance from the bower increases. Arranging objects in this way creates a forced perspective illusion,

which will affect the backdrop that the male displays against and may affect the female's size perception (Endler et al. 2010). Males that create higher-quality forced perspective illusions gain more mates (Kelley and Endler 2012a), suggesting that object arrangement is important (Fig. 2).

These males also manipulate the female's perception of color. They line the internal bower walls with red sticks, so that the female's eyes become adapted to red light when watching the male's display from inside the bower. This affects how she perceives the color of the decorations that the male displays (Endler et al. 2014).

Alongside the striking visual signal produced by males to attract a mate, some bowerbirds also produce a chemical signal. Male avenue building bowerbirds "paint" masticated vegetation onto the internal bower walls, and females nibble at this paint when inside the bower watching the male's display. This behavior has only been studied in satin bowerbirds, where the freshness of paint appears to be important in maintaining the signal (Bravery et al. 2006).

**Bowerbirds, Fig. 2** The bower of the great bowerbird (*Ptilonorhynchus nuchalis*), where objects on the display court are arranged by size to create a forced perspective illusion for the female inside the bower

## Mimicry

Many species of bowerbird are also proficient vocal mimics, for example, the spotted bowerbird *Ptilonorhynchus maculatus* can mimic up to 16 different species of bird, as well as human voices and other environmental sounds (Kelley and Healy 2011). Mimicry may function as a predator deterrent in some species that produce mimicry when disturbed or when sat on nests, such as the spotted bowerbird (Kelley and Healy 2012). Mimicry is a component of the courtship display in satin bowerbirds, where females prefer to mate with males that produce high-quality mimicry of a range of species (Coleman et al. 2007). Courtship mimicry has also been reported in at least six other species of bowerbird but is less well described in these species (Frith and Frith 2004).

## Bower Marauding

Bowerbirds can produce elaborate and dynamic sexual signals using their bowers as they have been removed from the constraints of having bodily ornaments such as brightly colored feathers. However, such non-bodily ornaments are more susceptible to disruption from rivals compared to more typical bodily ornaments. As females generally prefer males with lots of colored decorations on a well-constructed bower, a male can increase his attractiveness to females by stealing decorations and destroying the bowers of rival males (Borgia and Mueller 1992; Lenz 1994; Madden 2002). Such marauding behavior has a twofold benefit: it allows the marauder to increase the quality of their display while reducing the quality of his rival's display. The rival loses a decoration, and females will not enter his bower until it is repaired. However, the marauder takes a risk when he leaves his own bower unattended during marauding trips – his own bower is more susceptible to marauding from other males when it is left undefended. Males must therefore balance the risks and rewards of marauding (Pruett-Jones and Heifetz 2012).

Marauding rates vary among species, and species with bowers that are closer together seem to

maraud more. Males tend to maraud neighbors, probably because it minimizes the amount of time they leave their bower unattended. Males also don't seem to discriminate against kin or non-kin with their stealing behavior (Madden et al. 2004) and often have a reciprocal "tit for tat" stealing relationship with their closest neighbors.

## Female Choice

Bowers are an exploded lek-type mating system, where females can sample multiple males in a short amount of time. Female choice has only been studied in detail in satin bowerbirds, where females sampled lots of males early on in the mating season and then revisited a subset of males before making their final choice (Uy et al. 2001). Female bowerbirds may also be assessing different components of male displays as their interest in a particular male as a potential mate progresses. Mature females sampled a small handful of males and often revisited males that they had mated with in previous years. In contrast, younger, more inexperienced females sampled a wider subset of males before making their choice. Furthermore, females that chose very attractive males in the previous year typically chose the same male the following year, whereas females that made a poor choice the previous year spent more time searching for a more attractive mate (Uy et al. 2006).

## Bowerbird Cognition

It has been argued that the behavioral complexity exhibited by bowerbirds indicates enhanced cognitive ability and that bowerbirds can be considered to exhibit culture (Madden 2008). The polygynous bower-building species of bowerbird have relatively larger brains than the monogamous catbirds, and brain size also increases with increasing bower complexity (Madden 2001). However, more recent research suggests that the absolute number of neurons, not brain size, is important in explaining cognitive ability (Olkowicz et al. 2016).

There is conflicting evidence whether females within species base their choice of mate on his cognitive ability. Several studies on satin bowerbirds have reported a link between a male's problem-solving ability and his mating success (Keagy et al. 2009, 2011). However, there is no clear evidence of a link between general cognitive ability "g" (where males that are good at solving one type of cognitive test also perform well in others) and mating success, in this species or the closely related spotted bowerbird (Keagy et al. 2011; Isden et al. 2013). These conflicting results could be due to the complexity of identifying appropriate tasks that probe cognitive ability and different cognitive domains. It seems likely that there is some form of cognitive component to bowerbird sexual displays, as males learn how to build bowers and males vary in the quality of their bower constructions (Frith and Frith 2004). They also improve on other components of their displays as they age, suggesting that their displays are refined by experience over time (Collis and Borgia 1993; Kelley and Endler 2012b).

## Conclusion

Bowerbirds are a fascinating family of birds that exhibit some of the most elaborate courtship behavior in the animal kingdom. They offer an excellent system for examining a wide range of subjects including sexual selection, female choice, cognition, and social learning. However, there is still much that we don't know about bowerbirds given that only a handful of species have been studied.

University, Guizhou, China

## Which Animal Species Use This Behavior to Move?

A movement behavior of mammals, especially found in the all gibbons species (Hylobatidae) of primates, and include some other primates species, such as macaques, this primate species can jump-off the higher trees, and use their forearms to grab the branches of another trees, and stay in the canopies, some like the gibbons move behavior.

## Why Gibbons Choose This Type to Move?

Because all gibbons species live in the canopies of the higher arbors of the tropical rainforests or the subtropical evergreen broadleaf forests, they seldom go down and move on the ground. The reason is that they need to move from one tree to another tree, and if these trees are close, the gibbons would have to move a great deal longer, through a ground path. Therefore, this is typical adaptive behavior in the dense canopies of rainforests or subtropical evergreen broadleaf forests.

## How Do the Gibbons Fulfill This Behavior?

### Anatomical Structure

Gibbons use their long forearms to accomplish this behavior. For example, the species of *Nomascus leucogenys*, the whole-body length (measured from the top of the head to the anus) is between

45 and 62 cm, but their average forearm length is 76.4 cm (measured from the longest finger tip to the end of humerus, with the skeletal series of the forearm including: phalanx, ossa metacarpale, ossa carpi, ulna, radius, and humerus). Therefore, the forearm is longer than their whole body length. Meanwhile, the length of forearms is also longer than the lower limbs (average length 55.95 cm, measured from the longest toe tip to the end of femur, with the skeletal series of lower limb including: phalanx digitorum pedis, ossa metatarsi, ossa tarsi, fibula, tibia, and femur). Gibbons also have a well-developed clavícula (average length 10.6 cm) and scapula (average length 11.2 cm).

The major difference in the appendicular skeleton between gibbons and other primates species (include human beings) is basically that the ratio of head of radius to collum radius is larger. But there are many differences in the muscles of upper limbs among the primates species, including human beings. These difference reflect the adaptation in the brachiation behavior, including of the muscles on the shoulder-back, the muscles of the scapula, the muscles of the humerus, the muscles of the radius, and the muscles of the phalanx. For example: (1) cucullaris do not reach the occipital; (2) the pectoralis minor muscle has the clavicle end point; (3) the subclavius muscle starts at the second rib; (4) the musculus biceps brachii has three start points and do not start from the coracoid process; meanwhile, this muscle connect with the fibers of flexors of the forearm; (5) the musculus flexor digitorum sublimis has more ulna start points; (6) the musculus extensor carpi radialis longus always connects with the musculus extensor carpi radialis brevis, and the former has a tendon which ends at the first metacarpale; (7) the musculus extensor digitorum superficialis has the ulna start point; (8) the muscoli extensor digiti quinti proprius has the ulna start point; (9) no muscoli palmaris brevis; (10) the adductor pollicis not only ends at the phalanx but also ends at the metacarpales.

Because gibbons have these features of the forearm muscles, they could move among the canopies of the high trees. Other smaller primates, such as the macaques species, need to jump-off from higher position and then grab the branches. Gibbons, on the other hand, just use the two

forearms to grab the branches to move forward in the canopies.

## Brain Asymmetry

Sanjay Das  
National Institute of Mental Health and  
Neurosciences, Bangalore, India

## Definition

The brain for accurate and better functioning divides its labor by structural and functional asymmetry or lateralized by anatomical, physiological, neurochemical, psychological, and behavioral asymmetries.

## Introduction

Neuroimaging or lesion studies reveal the interesting fact that our daily activities which we perform consciously or unconsciously like preferences of ear for holding phone, foot preferences of the snowboarder, or inclination toward right hand during fine motor skills are related to brain hemisphere specialization also called lateralization.

## Evolutionary Theory of Brain Asymmetry

- (a) **Why asymmetry is required?** In general with few exceptions, the advantage of

asymmetry reflects more in motor than sensory input (Corballis 1998). Where bilateral control will decrease the conduction time between hemispheres, unilateral control will fasten the speed of performance (Ringo et al. 1994). Further advantage of unilateral over bilateral is that it avoids duplication and neural space wastage and increases the efficiency, and that's why left hemisphere is dominant for language and right hemisphere dominant for spatial attention (Mort et al. 2003). Duplication further may cause interhemispheric conflict (Corballis 1991).

- (b) **Why the variation in lateralization?** In general reverse asymmetry or lack of asymmetry is minor in a population. Direction of variation in asymmetry is either genetic or nongenetic not the matter, but it should be adaptive. Directional asymmetries may have frequency-based selection to have adaptive advantage. To escape from the predator in a group or flock, all the individuals turn in the same side, i.e., the selection (Ghirlanda and Vallortigara 2004), but the reversal may be advantageous in minority (Raymond et al. 1996). According to Annett (2013) and McManus (2002), one allele cancels rather than reverses asymmetrical influence of the other. The asymmetry and symmetry should have a proper balance because too much symmetry poses difficulty in neural programming for complex action and too much asymmetry leads to vulnerability. The balance is achieved during development. Environmental variation may attribute asymmetry, but genetic influences balance the asymmetry. In a single gene model, balance may be achieved by heterozygotic advantage (Annett 2013). In asymmetry, presence or absence is more interesting rather than opposite direction as found in a UK based study in 12,770 11 year old boys. It was reported that boys who lack clear handedness perform worse than either left- or right-handed on test of verbal and nonverbal ability, reading comprehension and mathematical ability (Crow et al. 1998). Lacking of directional allele in this case may run the risk of what is called "hemispheric indecision."

- (c) **Symmetrical oddity?** Symmetry may in some case provide cognitive adaptive advantage, but in a minority condition, oddity seems to provide creativity. Although mixed handers are weak academic achiever (Crow et al. 1998), they proved to be creative and have magical ideas (Barnett and Corballis 2002; Nicholls et al. 2005), and also they are at high risk of sensory illusion (Niebauer et al. 2002) and schizophrenia (Claridge et al. 1998; Upadhyay et al. 2004).

## Evolutionary Organization of Anatomical Asymmetry

### Expansion of Brain Size

Expansion and complexity raised in the brain over the evolutionary decades depends on the function it had to perform. In the need of functional incompatibility and simultaneous parallel processing of enhanced cognitive capacities, expansion promotes efficiency where duplication or repetition seems to be less important. Compartmentalization is the best option to avoid space competition of the different structure in the hemispheres for performing different activities rather than forming network within a single hemisphere. Consequently right hemisphere is specified for attention, memory storage as a global process, and left hemisphere for language. Further unilateral network develops in the larger brain due to corpus callosum for information transfer. Smaller callosal areas contain relatively thinner predominant tract in larger brain.

### Left Hemisphere Dominance as Volume Asymmetries

First asymmetries in left hemisphere are dominancy in language production and comprehension. Speech production and perception, the components of language are predominantly lateralized in left hemisphere. PT (planum temporale) an extension of Wernicke's area is ten times larger in left hemisphere and posits an example of left hemisphere lateralization. The only evolutionary and anatomical advantage of this lateralization is less time of language transfer

and avoidance of competition between hemispheres for controlling of speech muscle.

Second asymmetries lie in right-handedness for stereotyping behavior such as different movements and gestures associated with speech production in non-primates and early hominids as proposed by Condillac in 1746. Broca's area (area 44) which is associated with controlling muscle of the face and vocal tract is enlarged in great apes like chimpanzee and gorilla. Relation between gesture and language can be further validated by the Taiwan and Nicaragua children research on indigenous gestural language. Almost 97% of right-handers have their speech and language localized in the left hemispheres and remaining 3% left-handed are bilateral language presentation.

### Brain Asymmetry in Nonhuman Species

Brain asymmetry is not at all unique for human, a misconception carried by people for long. Rather brain asymmetry can be found in nonhuman primates, rodents, birds, and amphibia. Even left-right asymmetry is also found in invertebrates. Although distantly related, the brain lateralization associated with learning and retrieval of short-versus long-term memory in insects and birds is same. In *Drosophila* a small nucleus named Asymmetry body (AB) inside the brain found in the right hemisphere exhibits better long-term memory than *Drosophila* with bilateral AB. Similarly right antenna is showing efficiency for short-term memory and left antenna for long-term memory for odor preferences in honeybee (Rogers and Vallortigara 2008). In rat, mice, rabbits, and cats, the right hemisphere is slightly larger than the left. Mice with hippocampal asymmetry show decrease performance in spatial learning and memory. Behavioral asymmetry was also found in amphibian like toad that attacks their conspecific on the left side and prey to the right side (Vallortigara et al. 1998). Poeciliid fish shows behavioral asymmetry by turning right in presence of an opaque barrier but leftward preference confronting a predator (Bisazza et al. 2000). Passerine birds and frog utilize their left hemisphere

for song production and clasping vocalization. PT (planum temporale) asymmetry as well as longer and straighter Sylvian fissures on the left side has been found in nonhuman primates. In the epithalamus of many phyla like reptiles, frog, zebra fish and fish, a conserved neuroanatomical asymmetry has been documented (Concha and Wilson 2001).

### History and Background of Brain Asymmetry

In the middle of the nineteenth century, the pioneering work in the field of brain asymmetry was done by M Dax and P. Broca, and later Wernicke in aphasic patients showed that specific area of the brain is responsible for speech production and understanding language (Broca 1865; Wernicke 1874; Manning and Thomas-Antérion 2011). After the initial studies in aphasic patients, few decades after, lesion in different parts of the brain like lesion in the right brain is associated with decrease in emotional expression and inappropriate difference. Right brain injury reflects in left hemi-neglect affecting the left visual field unlike the left brain injury that doesn't affect right visual field. These suggest the asymmetrical nature of the brain. Further hemispheric specialization for other cognitive functions was best described by "split-brain patients" by Gazzaniga and Sperry (Gazzaniga 2005; Gazzaniga et al. 1962) where they disconnected the hemispheres by ablating the corpus callosum. Consequently lateral stimuli coming from one hemisphere are getting interrupted in free-flowing to the contralateral hemisphere. Equipped with these special features, each hemisphere activity of split-brain patients were addressed when they were given a task to perform and it was found that they couldn't recognize the object in their left visual field even by touching with their left hand. Surprisingly there was no problem with the right visual field. This confirms that the right brain perceives the information. In the coming decades, with the invention of noninvasive imaging techniques like PET (positron emission tomography), MRI (magnetic resonance imaging), and DTI

(diffusion tensor imaging), structural and functional asymmetries can be assessed in a better way by visualizing the gray matter structure, axonal tracts, and neuronal activities in the live brains.

## Few Important Facts of Brain Asymmetry

Prominent brain asymmetries can be dealt with the following important facts: petalias and related asymmetry, Sylvian fissure and related asymmetry, central sulcus and related asymmetry, ventricular asymmetry, and tissue component asymmetry.

## Types of Brain Asymmetry

### Anatomical Asymmetries

Anatomical asymmetry was first described by Geschwind and Levitsky in 1968. They reported that the left planum temporale underlying the Sylvian fissure near Wernicke's area was larger than the right in 70% of the right-handers which is left-hemispheric specialization of language. Pars opercularis (Broca's area) is larger on the left (Geschwind and Galaburda 1985).

The asymmetry in frontal and occipital lobe is quite demarcating in the two hemispheres such as the frontal region is wider and larger in the RH, whereas the occipital region is wider and larger in the LH. An asymmetry in dendritic organization was found in the left and right operculum (Scheibel et al. 1985) since left higher-order dendritic branching was greater, whereas right lower-order dendritic branches were longer. The reason behind quicker early RH development is its dendritic arborization, but after the first year of life, LH development is greater.

### Neurochemical Asymmetries

(a) Asymmetry in neurotransmitter: Neurotransmitter dopamine which is involved in motor activity and higher integrative function is lateralized to LH. Autonomic and psychological arousal controlled by noradrenergic and serotonergic neurons are lateralized in

RH. It can be said that LH is "activation regulatory" system, i.e., action-oriented controlling of the motor activity, and RH is "arousal regulatory" system, i.e., orientation to input stimuli which leads to attention control.

- (b) Asymmetry in neuroendocrine activity: During emotional situation, there is asymmetry in cortisol secretion (Wittling 1997; Davidson and Hugdahl 1995). A nice postulation can be derived regarding the gender-specific developmental asymmetry due to steroid hormone. Prenatal hemispheric asymmetry is affected by stable testosterone, whereas estrogen which is fluctuating affects the activation of neurotransmitter tracts and selectively changes callosal function.
- (c) Asymmetry in neuroimmune activity: Activation of LH seems to be immuno-enhancing, whereas RH activation leads to immunosuppression.
- (d) Asymmetry in brain receptors: Asymmetry in brain receptor like nicotinic acetylcholinergic receptors is lateralized predominantly in the right hemisphere. For example, some recreational drugs like alcohol, caffeine, and especially nicotine are uptaken predominantly in those nicotinic receptors in the right hemisphere. Some pharmacological agent like lithium bicarbonate, methylphenidate, and chlorpromazine also displays asymmetric hemispheric effect.

### Physiological Asymmetries

- (a) *Attention*: For sustained attention task activation of prefrontal and parietal segments is lateralized in the RH. Anterior cingulate cortex and left prefrontal cortex are engaged for spatial compatibility task, whereas visuospatial attention is engaged for the right parietal cortex. For divided attention task, left prefrontal cortex has been activated.
- (b) *Motor*: Left prefrontal-intraparietal areas are selectively active during unimanual choice. Dorsal premotor and superior parietal areas are responsible for spatial compatibility tasks, predominantly on the left, whereas hand movements and object manipulation activate bilateral.

- (c) *Perception*: Although perception of faces and object follows the same ventral pathway, there is more right lateralization for faces than object. For smell perception right lateralization of olfactory orbitofrontal cortex is involved. In case of visual perception, visual-form information is processed into the right occipitotemporal cortex or fusiform cortex, whereas for processing categorical information, left is important. Similarly right superior temporal cortex is responsible for processing of music, and left Broca's area/insula is for rhythm. Right prefrontal cortex is for self-selectivity recognition.
- (d) *Imagery*: Word to image generation involves the left inferior posterior temporal lobe, whereas complex imagery engages right temporal cortex. Imagery of maps involves right superior occipital cortex. Mental navigation involves the activation of left middle occipital gyrus.
- (e) *Language*:

- (g) *Emotion*: Emotions are lateralized into left prefrontal cortex. During masked (unconscious) presentation of conditioned fearful faces, lateralized right amygdala activates (Gazzaniga 2000), but during unmasked (conscious) presentation, left amygdala activates.

### Psychophysiological Asymmetries

Anatomical asymmetries reflect into cognition, emotion, and autonomic process regulation. Neurotransmitter, neuroendocrine, immunoregulatory, cardiovascular, skin temperature, and vasomotor activity are asymmetric. Neural control of cardiovascular function is lateralized.

Sympathetic and parasympathetic pathways control the peripheral autonomic chronotopic control of cardiac activity (heart rate). Auriculoventricular conduction and cardiac contractivity are left-lateralized. Further, emotional stimuli in the

left visual field yield larger heart rate, and blood pulse volume changes than stimuli in the right visual field. Pain sensitivity is greater in the RH.

### Behavioral Asymmetries

To measure the behavioral asymmetries or effect of lateralization input, stimuli were restricted and behavioral responses or both to one sensory or motor side. Hemifield tachistoscopes with unimanual responses is used to measure the symmetries.

### Determining Factors of Brain Asymmetry

#### Environmental Factors

Although genetic factors contribute in the lateralization of the brain, prenatal and postnatal environmental stimuli further trigger it.

*Light*: The best example and well-characterized illustration of environmental impact on brain asymmetry is the chick and pigeon asymmetric development of visual pathway which is light stimulus dependent (Rogers 1982; Rogers and Sink 1988; Manns and Güntürkün 1999). During the final day of development inside the egg, the embryo turns so that light passes through the right eye and can be stimulated and left hemisphere getting activated. If the right eye is occluded, it turns in such a way that left eye becomes stimulated and right hemisphere is getting activated. If the eggs are incubated in dark for last 3 days of hatching, asymmetry will not develop during choice of grains and pebbles. In case of zebra fish, Budaev and Andrew reported that the preference of avoiding or approaching predators depends on the early exposure of embryos to light. This light could also influence the developmental asymmetry of habenular nuclei not the visual pathway where absence of light delays the habenular nuclei (Borsetti et al. 2011).

*Fetal posture and orientation*: Due to mother's visceral asymmetry, the fetus in the final trimester lies toward the left in head-down position in the mother's womb which may be the reason favoring the right-hand dominance contributing motor lateralization. Language is lateralized by stimulating the right ear since it is close to the body wall.

*Hormones:* Some independent reports found that male borns in winter are left-handed (Stoyanov et al. 2011). High level of androgen in spring season along with genetic factors may contribute to induce a left shift during fetal development showing a genetic association between handedness and androgen receptor. Gender differences in human cerebral structural asymmetries and handedness prove the influence of sex hormone in brain lateralization in animal like fish (Bisazza et al. 1998). In frog seasonal changes influences the structural asymmetry in habenular nuclei (Kemali et al. 1990).

*Genetic factors:* Genetic contribution in hemispheric asymmetry is controversial. Asymmetry in hemispheric volumes are more influential in right-handers than left-handers.

Genetics of Brain Asymmetry

Handedness and language processing asymmetry were established early in development. Before the development of true language, perception and production of language are lateralized in infants. The hemispheric dominance for handedness and language skill which is an early onset phenomenon established in fetus and degree of heritability for handedness together suggest the genetic factors in brain asymmetry.

Genetics of Asymmetry of Handedness

Handedness is either multigenic trait or controlled by single gene with two alleles of which one is dominant for right-handedness and another one is recessive for left-handedness. Linkage asymmetry and genome-wide association studies (GWAS) reveal one of the gene LRRTM1 (leucine-rich repeat transmembrane neuronal 1). The minor alleles of this gene were found associated with handedness in families of schizophrenic patients but not in healthy controls (Francks et al. 2007). GWAS further report a specific SNP of PCSK6 (preprotein convertase subtilisin/kexin 6) in dyslexic patient (Scerri et al. 2010) rather than the orientation of handedness in healthy individuals. The gene encodes an enzyme involved in the maturation of Nodal/Tgfb factors has significant

role in body asymmetries also provides a link between body and brain laterality. Another evidence is that PCSK6 knockout mice display visceral heterotaxia (Constam and Robertson 2000). The association between handedness and gender, with males tending to be more represented among left-handers (Raymond et al. 1996), was shown by Medland et al., by showing an association between handedness and the number of polymorphic polyglutamine CAG repeats in the androgen receptor (located on the X chromosome).

Genetic of Asymmetry of Language

FOXP2 is one of the genes which is involved the language asymmetry. A series of SNP of FOXP2 is involved in speech impairment. Activation of different brain areas during reading involves a specific series of SNP of FOXP2. FOXP2 expression increases in area X in bird during song learning. Silencing of FOXP2 gene by RNAi results in inaccurate vocalization.

Gender-Specific Asymmetry

Greater functional lateralization in men than women due to less sharply defined hippocampal function or larger commissural system in women.

| Area                               | Asymmetric features                                                |
|------------------------------------|--------------------------------------------------------------------|
| Hemispheric volume                 | Larger in male fetuses                                             |
| Central sulcus                     | Deeper in the left hemisphere than right only in male right-hander |
| GM asymmetry                       | Found in male compared to female                                   |
| Parasagittal asymmetry             | In the anterior callosal body                                      |
| Planum parietale and inferior lobe | Rightward asymmetry                                                |
| Right frontal petalis              | Greater asymmetries in both right- and left-handers                |
| Occipital petalis                  | Asymmetry in left-handers only                                     |

Functional Adaptation

Brain asymmetries are not always genetically determined but rather depend on early frequent exposure of sensory or motor stimuli. It is due to experience-dependent plasticity and behavior

which influence the neuronal changes in two hemispheres. For example, using of one forelimb in the postnatal period causes larger neuropil volume and lower cell packing density in motor cortex. In mice with hereditary asymmetry in whisker pads, right whisker pad is dominant with left paw preference. It shows that limb preference is associated with asymmetry in sensory input. In human, right-handed keyboard player if trained bimanual from childhood performs better in motor skill test. The absolute length of central sulcus is also associated with the age of musical training. Those who started music at early life have longest sulcus at both sides. Here motor stimuli play the role of asymmetry.

Aberrant Asymmetries and Disease

| Disease                | Asymmetrical area                                                                                                                                                                                                                                                           | Comments |

|-------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | (typically worse on the left side) with relative sparing of the hippocampal formation                                                                                             |                                                                                                                                                                                          |
| Dementia          | Left hemisphere more susceptible                                                                                                                                                  | CSF volume in the left Sylvian fissure rises sharply than the right                                                                                                                      |
| Alzheimer disease | A spreading wave of GM loss emerges initially in entorhinal and temporal-parietal cortices, sweeping into frontal and ultimately sensorimotor territory as the disease progresses | This sequence occurs in both hemispheres, but left hemisphere regions are affected earlier and more severely. The right hemisphere follows a similar pattern approximately 2 years later |

Conclusion

Brain asymmetry evolved for proper and fast functioning of the brain from lower-order animals to higher-order animals including human. The asymmetries can be in the form of anatomical, physiological, psychological, neurochemical, and behavioral. Two cerebral hemispheres are lateralized for performing different functions. The brain asymmetries can be gender specific. The LH is found to be specialized for motor functions and the body’s defence regulation against invading agents whereas the RH is found to be specialized for controlling of functions to support survival and cope up with stress.

## Broken Wing Display

Miguel Angel Gómez-Serrano  
Generalitat Valenciana-VAERSA,  
Valencia, Spain

## Synonyms

[Distraction display](#); [Injury-feigning behavior](#)

## Definition

The broken wing display is a feigning behavior that some ground-nesting birds perform to lure a potential predator away from the bird's nest or chicks (Armstrong 1949a). The deception consists of pretending that the bird has a broken wing that hinders flight. If the predator is deceived and chases the bird, it will move away from the nest or chicks (Ristau 1991), thereby considerably reducing the probability of finding them. Finally, when the predator has been lured away from the nest, the bird puts an end to its distraction display and escapes.

## Description

Some ground-nesting birds employ distraction displays as part of their antipredator strategies because they nest in sites easily accessible to a wide range of predators. The aim of these behaviors is to divert predator attention away from

offspring, by drawing their attention towards false nests or an easy prey (Gochfeld 1984; Sordahl 1986; Byrkjedal 1989; Caro 2005). This deception can be articulated by displaying dishonest signals concerning their physical condition, e.g., simulating an injury that hinders their ability to escape.

The broken wing display is part of the different types of distraction behavior that birds can perform to deceive a potential predator (Armstrong 1949b). Since the deception consists of luring the predator towards a bird that is unable to fly, the behavior is displayed only against terrestrial predators, particularly mammals. There are multiple versions of distraction displays that can fit within the broken wing behavior category. However, all of them share abnormal wing movements which look like injuries to one or both wings (Gochfeld 1984), and impaired flight ability.

Although this behavior has been documented in several bird lineages, it reaches its pinnacle in

shorebirds. For this avian group, Gochfeld (1984) describes the broken wing display in different species. For instance, calidridine sandpipers perform their display running with wings half spread and with the fanned tail dragging on the ground. The plovers of the *Charadrius* genus are characterized by display with spread tail, creeping forward and beating one or both wings on the ground. But other plovers, such as the Killdeer (*Charadrius vociferous*), can extend one wing on its back and beat with the other on the ground (Gochfeld 1984).

Birds usually perform the broken wing display while moving along the ground, although they can alternate or end it with a stationary display (Ristau 1991). In both instances, some birds can use calls suggesting injury (Sordahl 1986). Some stationary displays performed by several plovers are intimately related to the broken wing display. For instance, some birds (e.g., the Kentish Plover, *Charadrius alexandrinus*) may remain motionless

**Broken Wing Display, Fig. 1** The sequence of images shows different types of behaviors performed by an adult male of Kentish plover (*Charadrius alexandrinus*) that are directly related to the broken wing display. The images

illustrate various snapshots during the performance of both mobile and stationary displays (Author: Miguel Angel Gómez-Serrano)

while keeping wings extended as if exhausted or shuffle wings rhythmically or spasmodically (Simmons 1951). The broken wing display is frequently alternated with other distraction behaviors like crouch-run, false feeding, or incubation-like displays (Simmons 1951; Gochfeld 1984) (Fig. 1). In fact, birds can modify the intensity and variety of their distraction behaviors depending on the response of the potential predator (Ristau 1991).

The distraction display usually begins at the end of egg-laying and its intensity increases with nest age (Sordahl 1986). Generally, the frequency of broken wing display intensifies as the hatching date approaches (Byrkjedal 1989), coinciding with a substantial time investment in incubation tasks by parents.

Birds performing distraction behavior incur a certain degree of risk. Nevertheless, this risk is mitigated by the fact that the performer is alert and aware of the predator. Indeed, distraction behavior is probably less dangerous than other antipredator strategies (e.g., mobbing), because it is usually performed at a greater distance from the predator (Sordahl 1990). Investment in antipredator defense increases offspring success (Caro 2005), but should be proportional to predation risk (Lima and Dill 1990). Although this trade-off must exist, there is a paucity of evidence supporting that risk assumption by parents has a positive impact on reproductive success (Byrkjedal 1987; Caro 2005; Gómez-Serrano and López-López 2017). Nevertheless, nest success has been shown to increase with the intensity of distraction displays in the Kentish plover (*Charadrius alexandrinus*), and there are differences in nest defense investment within pairs, with females performing riskier defensive behaviors than males, as is the case of the broken wing display (Gómez-Serrano and López-López 2017).

## Brood Defense

- Territory Defense

## Brooding

Ines Braga Goncalves  
University of Bristol, Bristol, UK

## Synonyms

Caring; Incubating

## Definition

A form of parental care behavior that occurs in egg-laying animals, during which a parent retains eggs within or near the body and provides heat, nutrients, oxygenation, and/or osmoregulation, as well as protection from predators to the developing embryos and hatched young.

## Introduction

The definition of brooding, like that of many other terms in zoology, has evolved over the years to broaden its applicability to a wider range of taxa. Strictly speaking, the word brooding means “to lie upon” and has been used since the fifteenth century to describe the behavior of hens sitting on eggs. In zoology, the term “brooding” was originally specifically used to describe a parental care behavior of birds that occurs after egg laying, in which a parent, usually the female, will sit on the developing embryos, keeping them warm until hatching. Nowadays, whilst the use of the term brooding is still limited to egg-laying animals (the equivalent in eutherian mammals being “gestation”) and parental care behaviors carried out whilst in physical contact with the offspring, its definition is no longer restricted to birds nor to heat transfer (= strict incubation). Brooding behaviors include the transfer of heat; the provision of nutrients, oxygenation, and/or osmoregulation; metabolic waste removal; maintenance of optimal humidity levels; and protection from predators to the developing offspring. These behaviors may be performed by the mother, the

father, or by both parents. At least in birds, egg laying promotes the secretion of several hormones and neurotransmitters that mediate behavioral and physiological changes that prepare the parent for brooding. These changes, together termed *broodiness*, include reductions in time spent drinking and feeding, increased tendency to incubate the eggs, and the plucking of feathers from the abdomen and chest that are used to cover the eggs. In doing so, broody birds develop a patch of featherless skin on their underside, aptly named a brood patch, that when in contact with the surface of the eggs, allows the parent to efficiently transfer body heat to the embryos. While it remains unclear whether all species that brood experience *broodiness*, brooding behavior is practised by most birds, monotremes (egg-laying mammals), several reptiles, amphibians, fishes, and invertebrates. There is also some evidence that Oviraptorosaurs, a group of dinosaur species that lived in the Cretaceous Period, used to brood their offspring. However, it is important to note that, among fish, many species provide parental care but do not brood per se despite being classified as brooders. This confusion likely arises from the fact that the mass of fertilized eggs a parent cares for is often referred to as a brood. Yet, while they may care for the brood, i.e., protect them from predators, ventilate them, and clean them, they do not care for the developing embryos or fry in or on their bodies. Examples include substrate brooding fishes. Also worth noting are the inconsistencies in the bird literature; some authors use *brooding* in reference to hatched chicks only, and *incubating* in reference to eggs only, while others refer to both phases of parental care as *brooding*.

## Evolution of Brooding

The importance of parental care to animal evolution can hardly be overstated. Investment in parental care affects the potential reproductive rate of individuals, which in combination with other factors can affect reproductive behavior, within-sex competition for mates, the mating systems displayed, and resulting intensity of sexual selection in each sex (Williams 1966; Trivers

1972). Ultimately, parental care has evolved because it improves the fitness of offspring and therefore increases the reproductive success of parents. Brooding, specifically, is assumed to have evolved in species that inhabit suboptimal, unstable, or dangerous environments for embryo development, and where the ability to protect, thermoregulate, and/or move the eggs significantly improves offspring survival. Evolution of brooding strategies has also been highlighted as a driver of speciation in some families (Jones et al. 2003). As discussed below, brooding is taxonomically widespread, mostly obligatory in the species where it occurs, diverse in expression, and incurs significant costs to the parents. Efforts to minimize some of these costs have led to the evolution of strategies, such as con- and interspecific brood parasitism, communal brooding, and brood reduction.

### Cost of Brooding and Counteracting Adaptations

Brooding incurs significant fitness costs to parents. For example, brooding has been associated with increased adult susceptibility to predation in several species (Shine 1980). However, the reduction of energy reserves, coupled with the loss of opportunities to replenish them, is likely to be the most common cost of brooding. For example, mouthbrooding cichlids cannot feed during brooding, and the resulting loss in condition delays them from breeding again. Even in species where parents can feed throughout brooding, declines in body condition have been documented. In several species of the pipefish family Syngnathidae, brooding males can absorb some of the eggs in their brood pouches, a strategy akin to filial cannibalism and a type of brood reduction, which is assumed to slow down reductions in paternal body condition. Brood reduction also occurs in many species of birds. When, for one reason or another (e.g., detrimental environmental conditions), the cost of brooding all offspring increases to the point that brooding fewer offspring is expected to result in a higher fitness payoff, then parents are expected to reduce the total number of offspring cared for (Lamey et al.

1996). Hatching asynchrony, where eggs hatch days apart, and variation in egg size, with the resulting variation in offspring size are two adaptive strategies employed by females of several bird species to optimize brooding effort and facilitate brood reduction (Clutton-Brock 1991). Maintaining offspring temperatures can be energetically costly in birds; it has been estimated to raise adult basal metabolic rates by up to 40% in some species. Yet, without some form of thermoregulation, embryos cannot survive.

Several species have evolved strategies to either minimize or entirely bypass brooding, despite brooding still being essential for their offspring survival. Conspecific brood parasitism, where females lay eggs on other female's nests, has been documented in several species and, in some cases, has been associated with a bias to parasitize nests of kin (i.e., genetically related females). Arguably more extreme, interspecific brood parasitism occurs in some bird, fish, and insect species. In these cases, individuals deceive individuals of other species into brooding their offspring, resulting in an evolutionary arms race where the "parasite" species evolve strategies to successfully deceive their hosts, and "host" species evolve adaptations to identify parasitic eggs (Rothstein 1990).

### Diversity of Brooding Behaviors

Brooding behavior can take an enormous variety of forms. Below are some examples across the animal kingdom.

*Ectothermic thermoregulation:* All python species display extended maternal brooding, with females coiling tightly around the eggs, providing protection from predators during development. In addition, brooding has been shown to have two other functions in pythons: water balance regulation and thermoregulation, although not all species accrue all the benefits. To the surprise of the scientific community in the 1830s when it was first reported, females of several species thermoregulate their eggs, keeping them within narrow temperature ranges despite experiencing variation in ambient temperatures (Vieira de Andrade et al. 2016). For example, Burmese python (*Python bivittatus*) females

increase their metabolism and body temperature by contracting their muscles in a twitching fashion. Other species, such as reticulated pythons (*P. reticulatus*) increase their body temperature through physiological means, without visible muscle contractions. Others still, such as ball pythons (*P. regius*), thermoregulate through behavioral means: females bask in the sun to raise their own body temperature and then return to brooding the eggs and transfer their body heat. Recent research has also shown that brooding allows females to regulate clutch evaporative water loss, minimizing egg desiccation and promoting egg viability.

**Gastric brooding:** Sadly both now presumed extinct, females of the Australian frog species *Rheobatrachus silus* and *R. vitellinus* displayed a most peculiar and unique form of brooding: stomach or gastric brooding. Females would swallow the fertilized eggs and brood them in their stomachs for up to 6 weeks, during which time they could not feed. At the end of the brooding period, the females would literally regurgitate fully developed offspring (Greven 2011).

**Skin incubation:** Skin brooding has evolved independently multiple times in anurans, with the genera *Pipidae* and *Gastrotheca* displaying the most remarkable adaptations. In the Suriname toad (*Pipa pipa*), females brood the embryos in temporary brood chambers that form on the skins on their backs. After attachment, the embryos bury through the skin becoming fully imbedded. The physiology of the skin changes in preparation for reproduction and throughout brooding, becoming thicker, looser, and highly vascularized to accommodate the embryos and enable nutrient and gas transfer, as well as metabolic waste removal. At birth, fully developed toads emerge from the chambers, which are then shed before the cycle is repeated. In contrast, females of *Gastrotheca* species, widely known as marsupial frogs, have permanent dorsal brood pouches. After the eggs are fertilized, the male inserts them into the female's brood pouch, and highly vascularized brood chambers within the pouch develop around the embryos, facilitating the transfer of oxygen during brooding (Greven 2011).

**Fish pregnancy:** Arguably, the most complete and complex type of brooding is provided by

males of the *Syngnathidae* family, the seahorses, pipefishes, and sea dragons. During mating, females transfer the eggs onto the males, who provide all the care until the offspring emerge as mostly developed and fully independent juveniles. Depending on the species, males may brood the developing offspring on a patch of skin on their trunk or tail, or in a brood pouch, with more complex types of brood pouches enabling males to provide greater care. During brooding, the brood pouches change morphologically and physiologically, forming highly vascularized cup-like depressions around the eggs that ensure the supply of nutrients, oxygenation, and osmoregulation to the embryos in addition to metabolic waste removal, equivalent to mammalian placentas (Stölting and Wilson 2007).

**Mouthbrooding:** Oral incubation, buccal incubation, or mouthbrooding has evolved independently multiple times and across the animal kingdom and can be performed by both sexes. Mouthbrooding occurs when a parent cares for its offspring in its mouth for extended periods of time, preventing it from feeding during that period. In some species, parents begin mouthbrooding immediately after the eggs are fertilized (ovophiles), while in others mouthbrooding occurs only at the larval stage (larvophiles).

## Bruce Effect

Katherine Saxton  
Department of Biology, Santa Clara University,  
Santa Clara, CA, USA

## Synonyms

[Pregnancy block](#); [Reproductive suppression](#)

## Definition

Prevention of implantation or termination of pregnancy when offspring survival is threatened (e.g., by presence of a novel male).

## Introduction

The Bruce Effect was first described by Hilda Bruce in 1959, as a decline in pregnancy success when female laboratory mice were exposed to novel males soon after mating. This particular form of pregnancy delay can be considered in the context of reproductive suppression, a collection of adaptive strategies by which females delay pregnancy to increase their chances of reproductive success. Since 1959, the Bruce Effect has been documented in multiple species, both in the laboratory and in the wild. Biological mechanisms and the timing of the effect during gestation vary by species. The Bruce Effect can be generalized to describe reproductive suppression in response to threats to child survival.

## Bruce Effect in Mice

When exposed to unfamiliar males soon after mating, a high proportion of female mice end their pregnancy (Bruce 1959). Pregnancy block (i.e., prevention of implantation) occurs in up to 80% of female mice exposed to novel males in the laboratory, followed by a return to estrous and the ability to mate with the new male (Bruce 1961). Exposure must occur during the first 5 days after breeding; exposure to a novel male outside of this critical period will not induce the Bruce Effect, as implantation will have already occurred. The threat of the novel male is communicated via pheromones in the male's urine, and the Bruce Effect can be induced via exposure to the urine, even without the physical presence of the male (Dominic 1966).

## Adaptive Reproductive Strategy

The Bruce Effect is one mechanism of reproductive suppression. The model of reproductive

suppression describes several strategies through which females can prevent or delay pregnancy when future environmental conditions are likely to better support offspring survival, compared to current conditions (Wasser and Barash 1983). Thus, utilizing strategies of reproductive suppression may maximize the lifetime reproductive success of a female, even at the expense of short-term reproduction.

The Bruce Effect may have been conserved both as a result of competition between males and as a female strategy to avoid infanticide. New males may gain a fitness advantage by gaining the opportunity to reproduce (Schwagmeyer 1979), and females may both prevent investment in young at risk of death and make themselves available to reproduce again as quickly as possible (Labov 1981). In mice, some males engage in infanticide and kill offspring fathered by other males. Therefore, the female strategy of blocking pregnancy upon arrival of a novel male may prevent infanticide and allow the female to reproduce with the new male, thereby increasing the chance of her offspring's survival (Beehner and Lu 2013). Thus, the Bruce Effect can be considered an adaptive reproductive strategy (Labov 1981).

## Generalized Bruce Effect

Since it was first documented, the Bruce Effect has been observed in multiple species, including several species of rodents in the lab and in the wild (Schwagmeyer 1979), as well as primates (Beehner and Lu 2013). Although the Bruce Effect in mice occurs via pregnancy block, other species use different physiological mechanisms at different time points in pregnancy to achieve similar outcomes. For example, pregnancy block occurs before implantation (i.e., several days after breeding), but the Bruce Effect operates via pregnancy termination throughout gestation (i.e., up to the third trimester) in primates (Roberts et al. 2012). Taken together, these adaptive pregnancy disruptions comprise a larger set of reproductive strategies to prevent investment in offspring with low probability of survival.

The fraction of gestations terminated under the Bruce Effect varies across species and contexts

but can reach up to 80% in laboratory mice (Bruce 1961) and wild geladas (Roberts et al. 2012). The observation that some proportion of offspring survive suggests females may possess the ability to read and interpret environmental threats and to noncognitively control their response to threatening environments.

Threats beyond infanticide by novel males also lead to Bruce-like effects. These generalized Bruce Effects may be induced by social stress, subordinate rank, and high levels of female competition (Beehner and Lu 2013), as well as risk of predation and other ethologically-relevant stressors (de Catanzaro and Macniven 1992). A generalized Bruce Effect has also been identified in human populations, as increases in child mortality predict reproductive suppression via pregnancy termination (Saxton et al. 2017). Thus, the generalized Bruce Effect includes a range of noncognitive strategies to delay reproduction until environmental circumstances better support offspring survival.

## Conclusion

The Bruce Effect is one form of reproductive suppression, in which females block or terminate pregnancy to increase their lifetime reproductive success. In laboratory mice, the Bruce Effect was first identified as prevention of implantation in the presence of a novel male soon after mating. Pregnancy block under similar circumstances has since been recognized in other rodent species, while pregnancy termination at later stages occurs in a range of species. Reproductive suppression and the Bruce Effect increase maternal fitness by minimizing investments in offspring least likely to survive. A generalized Bruce Effect can describe a larger set of adaptive reproductive strategies, across multiple species, to prevent or terminate pregnancy when the environment threatens offspring survival.

## Bucket Experiment

Elske van der Vaart  
Cognitive Science and Artificial Intelligence,  
Tilburg University, Tilburg, The Netherlands

## Synonyms

Begging paradigm; Requesting paradigm; Visual attention paradigm

## Definition

An experimental setup designed to test for the ability to distinguish between “seeing” and

“non-seeing” individuals, for instance, by begging more from an experimenter with a bucket on her shoulder than from one with a bucket over her head.

## Introduction

In 1996, Povinelli and Eddy published a landmark series of experiments designed to test chimpanzees’ understanding of “seeing.” Eight young chimpanzees were trained to “request” food from a human experimenter. This involved extending an upturned palm through a hole in a plexiglass partition, similar to a “begging” gesture also observed in wild chimpanzees. Then, during test trials, the subjects were presented with two experimenters side by side, one of whom could see them and one of whom could not.

While the chimpanzees immediately preferred to beg from experimenters who were facing them, relative to experimenters whose backs were turned, they did not discriminate between experimenters covering their ears versus their eyes with their hands, those with blindfolds over their mouths versus their eyes, or those with buckets resting on their shoulders versus placed over their heads.

Povinelli and Eddy (1996) interpreted these results as evidence that chimpanzees likely learn specific contingencies – such as “gesturing towards another’s back is always fruitless” – without abstracting such “behaviorist” rules into a more general concept of what it means to “see.” Had they possessed such a concept, the study authors argued, they would have understood the relationship between line of sight and the ability to respond to requests and always preferred the “seeing” experimenter.

This conclusion has since been the subject of much debate. Firstly, it has been argued that the performance of Povinelli and Eddy’s (1996) chimpanzees is not representative of the species and, secondly, that the setup itself is fundamentally unsuitable for studying chimpanzees’ understanding of “seeing.” Despite this, variants of Povinelli and Eddy’s (1996) basic “bucket test” have now been used with a wide variety of

species, cementing its status as an extremely influential experimental design.

## Overall Chimpanzee Performance

Over the course of 13 experiments, Povinelli and Eddy's (1996) chimpanzees were exposed to 8 different configurations of seeing versus non-seeing experimenters. In the first four trials of each condition, they were above chance only for "front facing" versus "back turned." However, the subjects did eventually learn the correct preference in a number of other conditions, including "screen next to face" versus "screen in front of face" and "looking back over shoulder" versus "looking away over shoulder."

The overall pattern of results led Povinelli and Eddy (1996) to conclude that their chimpanzees had learned a "face rule" – "gesture towards the experimenter whose face is visible" – and were perhaps in the process of learning an "eye rule," "gesture towards the experimenter whose eyes are visible." Yet, when retested several years later (Reaux et al. 1999), these chimpanzees still did not immediately and flexibly discriminate between "seeing" and "non-seeing" experimenters.

However, the chimpanzees tested by Bulloch et al. (2008) *did* immediately perform above chance in many of the same comparisons, including "mixed" ones, such as "screen next to face" versus "bucket overhead" and "blindfold over mouth" versus "eyes closed." The exceptions were "eyes open" versus "eyes closed," where the chimpanzees did not initially show a preference, and "eyes closed" versus "looking back over shoulder," where they begged significantly more from the "non-seeing" experimenter.

To Bulloch et al. (2008), these results implied that their chimpanzees were sensitive to both the visibility of the experimenter's face and the visibility of her eyes but that the chimpanzees responded more strongly to the former cue. Furthermore, the authors hypothesized that the difference with Povinelli and Eddy's (1996) chimpanzees was caused by their animals' exceptionally rich social and physical environment. This could have enhanced their cognitive

development relative to the original group of juvenile subjects, who, for example, lacked direct access to mixed-age conspecifics.

However, subsequent research suggests subtle experimental differences might have played a role. It has been argued that "choosing between two experimenters" is itself very difficult for chimpanzees (Kaminski et al. 2004), and follow-up work has involved trials with only a single experimenter at a time (Kaminski et al. 2004; Hofstetter et al. 2007; Tempelmann et al. 2011; Hattori et al. 2011). In this setup, it is compared across trials whether chimpanzees gesture more toward a "seeing" experimenter than a "non-seeing" one.

Using this modification, Hattori et al. (2011) have found that chimpanzees do not discriminate between "eyes open" and "eyes closed" experimenters when requesting food visible on a table but that they *do* gesture more toward "seeing" experimenters when requesting food held in their hands. This corresponds to the fact that Povinelli and Eddy's (1996) chimpanzees had more difficulty with the original task than Bulloch et al.'s (2008), as the former used the "table" setup and the latter the "hands" version.

Across all "bucket test" variants, it appears that chimpanzees are sensitive to the visibility of an experimenter's face and, to a lesser extent, her eyes when requesting food that she is already holding (Hofstetter et al. 2007; Bulloch et al. 2008; Hattori et al. 2011) but that they respond most strongly to the orientation of her body when requesting food that is offered nearby (Povinelli and Eddy 1996; Kaminski et al. 2004; Tempelmann et al. 2011).

This has been interpreted as evidence that the "table" version of the task is more difficult for chimpanzees, perhaps because it is less clear that the experimenter is already willing and able to provide them with food. Then the task becomes more complicated than simply attracting the attention of the correct experimenter, and the chimpanzees' ability to respond to subtle cues of 'who can see them' might be masked (Kaminski et al. 2004; Tempelmann et al. 2011).

What the chimpanzees' performance on these various versions of the "bucket test" implies for

their understanding of “seeing” as a mentalistic concept, as Povinelli and Eddy (1996) originally set out to determine, remains controversial, as discussed next.

## The Wrong Kind of Experiment

The first critique of Povinelli and Eddy’s (1996) “bucket test” came from Hare (2001), who argued that experimental setups are only “ecologically valid” if they mimic subjects’ evolutionary history or daily life experience; only in such situations are animals likely to demonstrate the full range of their cognitive abilities. The “bucket test” appears to fail this criterion, as chimpanzees rarely share food in the wild.

However, it has been argued that “low ecological validity” is in fact a desirable feature in a cognitive test (Povinelli and Vonk 2004). The “bucket test” was designed to probe chimpanzees’ understanding of “seeing” as a subjective inner experience, in order to determine whether they have a “theory of mind.” Given this objective, an “unnatural” setup might be preferable, as it decreases the likelihood that the task can be solved by either innate rules or prior learning, instead of explicit reasoning about mental states.

Going further, it has been argued that the “bucket test” is fundamentally unsuitable for assessing animals’ understanding of “seeing” as it does not dissociate between “seeing” as a mental concept and “line of sight” as an observable behavior. That is, to “pass” a “bucket test,” it is sufficient for the subject to prefer experimenters whose eyes are visible and oriented toward them; it is not necessary for the subject to additionally have any concept of what it means to “see” (Povinelli and Vonk 2004; Lurz 2009).

## Beyond Chimpanzees

Since Povinelli and Eddy’s (1996) original study on chimpanzees, many species have been exposed to the “bucket test” and its variants. Other great apes, that is, bonobos, gorillas, and orangutans, appear to act broadly similar to chimpanzees

(Tempelmann et al. 2011). Other species of primate have shown diverse responses, with, for example, tufted capuchin monkeys sensitive to the visibility of the experimenter’s eyes (Hattori et al. 2010) but red-capped mangabeys differentiating only on the basis of her body orientation (Maille et al. 2012). Other work has focused on a variety of domestic species, including dogs (Gacsi et al. 2004), horses (Proops and McComb 2010), and pigs (Nawroth et al. 2013), with all three showing some sensitivity to the visibility of the experimenter’s eyes or face.

## Conclusion

Povinelli and Eddy’s (1996) “bucket test” was designed to investigate young chimpanzees’ understanding of “seeing.” It had the animals choose which of the two experimenters to beg from, where, for instance, one was wearing a bucket on her shoulder and the other a bucket over her head. While the initial group of subjects often failed to prefer the “seeing” experimenter, subsequent work has shown that chimpanzees are at least somewhat sensitive to the visibility of the experimenter’s face and eyes when deciding whom to approach. Whether this implies that chimpanzees have any concept of “seeing” as a mental state remains controversial. Nevertheless, the “bucket test” is still a popular experimental setup for research on animal “theory of mind,” with results now available for many different species.

## Bud

### ► Budding

## Budding

Pratiti Roy

Department of Genetics and Plant Breeding (Plant Biotechnology), Banaras Hindu University, Varanasi, Uttar Pradesh, India

## Synonyms

Asexual reproduction; Bud; Development; Growth

## Definitions

Budding may be defined as a process of development of an outgrowth in any organism. Budding leads to the formation of new living cells as the outgrowth eventually gets detached from the mother cell. Hence, it is considered as a method of asexual reproduction. It is mainly witnessed in yeast (*Saccharomyces cerevisiae*) and also in Cnidarian organisms like *Hydra* sp., sponges, corals, and echinoderm larvae. Organelles like mitochondria can also divide by budding.

## Mechanism of Cellular Budding

The cell first grows in size, and the nucleus is duplicated as an outgrowth and is visible at any end of the mother cell. Movement of the new nucleus to the bud like outgrowth and subsequent detachment of the daughter cell results in completion of budding. The new cell forms a clone of the parent and can have identical behavior and functions.

Angert (2005) has discussed the various models of budding in prosthecate  $\alpha$ -proteobacteria and *Planctomyces*, Gram-positive bacteria (with low GC content), and *Cyanobacteria* in detail, although

the molecular mechanisms are yet to be elucidated. Different bud-developing  $\alpha$ -proteobacteria like *Ancalomicrobium*, *Hyphomonas*, and *Pedomicrobium* have their own patterns of bud formation. Cellular asymmetry is essential in forming buds in bacteria; hence *Hyphomonas* is an organism of interest.

### Mechanism of Budding in *Hydra*

Asexual propagation in *Hydra* is mediated by exporting tissues into a bud, which detaches after 4 days after fully differentiating into a young polyp. A prerequisite for this detachment is the activation of fibroblast growth factor receptor (FGFR) signaling, the mechanism enabling constriction and tissue separation within the monolayered ecto- and endodermal epithelia. In *Hydra*, asymmetric cell changes are mediated by Rho, ROCK, and Myosin II via a novel pathway at its bud base to allow a basal constriction (Holz and Apel 2017). Actomyosin interactions and pathways controlled by RhoA, ROCK, and myosin (Fagotto 2014) allow tissue separation in embryonic systems.

### Budding in Yeast

In yeast, both haploid and diploid cells reproduce by budding. A small outgrowth emerges from the mother cell, the bud, enlarges up to a particular size, and finally separates from the mother cell. It has been reported by Nelson (2003) that in eukaryotic organisms like yeasts (*Saccharomyces cerevisiae*) cellular asymmetry determines the site of bud development and facilitates it by deposition of materials at that site to allow bud growth. Yeast cells undergo polarized growth during budding, their bud sites being selected differently depending on ploidy: haploid or diploid. Diploids bud in bipolar manner and haploids in an axial manner. In the axial budding pattern, proteins such as Bud3 and Bud4 may function as a transient spatial cue (Chant et al. 1995; Sanders and Herskowitz 1996). Mating is also facilitated in haploid yeasts (*Saccharomyces cerevisiae*) due to axial budding pattern. Bipolar budding is

required for formation of a branched colony under nutrient-restricted environment (Wang et al. 2017).

### Mitochondrial Budding

Dynamin-related protein (Drp1) and endoplasmic reticulum have been shown to play key roles in mitochondrial budding. Previously, electron micrographs and fluorescence images were used, but cryo-electron tomography has opened a whole new method to explore the underlying molecular mechanisms of budding in the frozen HeLa cells (intact) (Hu 2014).

### Conclusion

Budding refers to a promising new area of growth in any organism which forms a projection in cells. Researchers have thrown light so far in the different prokaryotes and eukaryotes even on eukaryotic organelle; yet many more pathways are still left to be identified and discussed. Artificial non-living model cells have been designed mimicking the living cells that gave rise to daughter vesicles with distinct interior and membrane compositions, done to study the mechanism of budding and asymmetric cell division in one-celled entities (Koback and Keating 2011). Recent research on electrochemical regulation in budding of yeast cells have been identified, which contributes to the cell polarity and bud formation (Haupt et al. 2014). Budding being an exclusively asexual reproductive means, the newly synthesized part lacks genetic variability. This has been both of a boon and a bane; boon to maintain genetic fidelity in the subsequent organelles like mitochondria but a bane abolishing genetic diversity in *Hydra* and many prokaryotes.

## Bushmeat Trade

James A. Oxley

Independent Researcher, Measham, Swadlincote, UK

It has been estimated that people have been hunting wildlife within tropical forests for 100,000 and

40,000 years in West and Central Africa and Asia, respectively, and the practice continues today (Milner-Gulland and Bennett 2003; Corlett 2007). In the present day, meat from wild animals that have been hunted, often illegally, for the purposes of consumption for protein (due to the lack of alternative meat sources) and/or to be sold or traded is defined as “bushmeat” (also known as “wild meat”). It is important to highlight that species are not restricted to terrestrial animals, for example, sea turtles and minke whale are also hunted (aka. “marine bushmeat”; see Clapham and Van Waerebeek 2007). Hunting for the purposes of bushmeat has been found to occur mainly in rural and developing areas of Africa, Asia, Oceania, and South America (Ripple et al. 2016). Bushmeat is commercially traded and often regarded as a luxury meat within urban areas. Consumption is driven by taste and the perception that bushmeat is healthier than commercially farmed animals (Van Vliet et al. 2017); however, there is a lack of information on the nutritional content of different forms of bushmeat. Despite this, Van Vliet et al. (2017) found that bushmeat has a positive impact on general dietary intake.

There are a wide range of taxa which are hunted for bushmeat, which will of course differ between regions, some of which include primates, ungulates, carnivores, marsupials, ratites, rodents, birds, reptiles, bats, and marine animals (Clapham and Van Waerebeek 2007; Pangau-Adam et al. 2012; Ripple et al. 2016). Specific species are likely to be more sort after within certain locations, such as primates in Central and West Africa (see Kurpiers et al. 2016), due to a range of factors such as species availability and demand, meat content, ease of capture, etc. Other factors include the availability of alternative food supplies, such as fish, as Brashares et al. (2004) found that in Ghana an increase in the frequency of bushmeat hunting and demand were found to be linked with poor regional fish supplies. Animals may be hunted for bushmeat and for a number of other reasons. For example, it has been previously estimated that approximately 13%, of 1331 bat species, are hunted for a variety of reasons such as medicinal, sport, ceremonial, with the main reason being for the purpose of consumption (Mildenstein et al. 2016).

According to Lindsey et al. (2012), the most common method used in Africa for bushmeat hunting is the use of snares. This was also found to be a commonly reported hunting method (alongside bow and arrows) as described in interviews of 147 hunters from 21 villages in Indonesia (Pangau-Adam et al. 2012). The popularity of snaring is likely to be due to the cheap cost, the fact that the equipment can be reused, and it catches live animals which is beneficial for communities which require specific slaughter methods (i.e., religious purposes (halal)) (Hennessey and Rogers 2008). However, snaring can result in a slow and painful death for the animals caught (e.g., pigs have been noted to be alive for up to a week when caught in a snare) and are indiscriminate about the animals it captures (Pangau-Adam et al. 2012). Additionally, there are a broad range of other hunting methods used, which may differ from region to region and many of which may be illegal. Other methods include traditional hunting methods (e.g., spears, bows and arrows), guns/firearms (e.g., air rifle), poison, pitfall/gin traps, felling trees, the use of dogs and fire (Pangau-Adam et al. 2012; Lindsey et al. 2012). The transport of bushmeat for the purposes of trade is likely to occur via road (facilitated by logging roads), trains, river, or by foot. However, little research has investigated methods of transportation and packaging methods, which could present potential issues for the contamination of bushmeat (Van Vliet et al. 2017).

As a result of increased bushmeat hunting due to a growing human population near forested regions and increased accessibility (e.g., logging roads), many species are currently threatened (e.g., western and Lowland Gorilla (*Gorilla gorilla*)) with extinction. To date, bushmeat has resulted in the extinction of a range of species (e.g., Miss Waldron's Red Colobus (*Piliocolobus waldronae*)) (Jost Robinson 2017). It has been previously estimated that per year five million tonnes of bushmeat are extracted for food in the Congo and Amazon basin alone (Fa et al. 2002). However, figures vary widely or are simply unavailable. Despite this, given the increase in

human population and associated demand for bushmeat within these regions, the term the "bushmeat crisis" has been coined and this type of hunting is generally regarded as an unsustainable activity.

## Human Health

Human health concerns associated with bushmeat may vary in risk and may include (i) contact via hunting, transport, (ii) butchering and meat preparation, and/or (iii) consumption of meat. Such activities have been previously linked to a range of emerging infectious diseases such as Ebola, HIV, and a range of other pathogens most likely facilitated by the increasing commercialization of bushmeat (Kurpiers et al. 2016). For example; Pourrut et al. (2011) surveyed the prevalence of gastrointestinal parasites in primates within three bushmeat markets within Yaounde City, Cameroon, and house kept pet primates within three towns in Cameroon. In total, of the 125 primates, relating to 15 different species, 78 were held for the purposes of bushmeat and 47 kept as pets. Twelve species of parasites were detected including seven nematodes, three protozoa, one cestode, and one trematode. It was found that wild primates were found to have significantly more helminths (92%) than those kept as pets (51%). Of the parasites found, route of transmission would occur either transcutaneously or via oral transmission, indicating that those individuals who consume or are involved in the butchering of bushmeat are at an increased risk of infection. Disease transmission has been noted to be of highest risk during the butchering of an animal (Van Vliet et al. 2017), although disease transmission can occur during the manual transportation of animals, if injured by an animal or during butchering. While Kamins et al. (2015) found that of the 95 hunters who came into contact with bats all of which had been scratched, came into contact with the animals blood and three individuals reported to have been bitten by bats highlighting the risk of disease transmission. More research is needed to investigate the human health risks related to

aspects of hunting methods used, the transportation of animals used for bushmeat to markets, and the preparation of meat for consumption (Wolfe et al. 2005).

Kamins et al. (2015) surveyed and interviewed 577 individuals in Ghana who were involved in the trade (hunting, selling, and/or consuming) of bats for bushmeat. The study found that no protective equipment, such as gloves, were worn by any of the hunters. Of the 132 individuals that stated to prepare bats for food, 37% stating to gut the bats prior to cooking. Furthermore, only 23% of all respondents perceived a disease risk from hunting, butchering, or eating a bat. Whereas, Friant et al. (2015) found that 55% of respondents within Nigerian communities thought that wild animals could transmit disease, yet only 26% took precautionary measures with only 3% utilizing protective clothing and less than 1% cleaning the meat. Clearly an increase in public health education is required. Friant et al. (2015) suggest that word of mouth and radio educational intervention would be the most appropriate avenues in Nigeria, and the exploration of novel, culturally acceptable protection methods requires further research.

## Tackling the Problem

Hunting wild animals for the purposes of consumption is a complex issue. Not only are there multiple factors coexisting alongside increasing hunting and commercialization, such as deforestation, loss of biodiversity, and habitat destruction, but there are also concerns from a human health aspect because of food security and emerging zoonotic and infectious diseases. Furthermore, stakeholders not only include hunters but also intermediaries, retailers, and the consumer.

As a primary source of protein, the availability of bushmeat clearly plays an important role within rural communities. A number of ways have been proposed to tackle the bushmeat crisis. For example; Wilkie and Godoy (2000) note that if cheaper meat alternatives are made available, then a decrease in hunting and improved conservation

could be seen. Gruber (2016) highlights that rodents, normally regarded as pests, could be used as a form of “mini-livestock” due to their small size and easy management. Many parts of Africa and South America currently hunt rodents, such as Cane rats (*Thryonomys swinderianus*) which can weigh up to 10 kg (Gruber 2016). The development of alternative protein sources could also be introduced through sustainable aquaculture and farming of both domestic and indigenous animals. However, farming of animals may require much more time and money in comparison to illegal hunting, which may already be well-established (Lindsey et al. 2012).

While the assessment of species is required, an emphasis on hunting of sustainable species would be beneficial from a conservation perspective. Further efforts are needed by governments with support from the international community to reduce the occurrence of illegal hunting, especially where species are under threat of extinction by imposing stricter laws and deterrents and ensuring appropriate enforcement. Kamins et al. (2015) note that alone laws and fines are unlikely to initiate sufficient changes and the potential health risk was more likely to act as a deterrent in comparison. Furthermore, the elimination and control of trade routes of illegal bushmeat and overseeing market produce is also required by local and national authorities. Human population assessment and planning near effected and protected areas may help in finding appropriate solutions. While emphasis is generally placed on individual countries, international involvement is required to support countries dealing with the bushmeat crisis. Overall, it is likely that a combined and interdisciplinary approach is required including, education, law enforcement, land/family planning, alternative food (farmed animals) and income sources (e.g., ecotourism), and improved conservation planning and protection (Lindsey et al. 2012). Other closely related areas also need to be incorporated, such as animals used for medicinal purposes and prevention of disease through public health research and initiatives (e.g., education about hygiene practices during food preparation).

Conwy Lloyd Morgan (Fellow of the Royal Society) was a British zoologist and psychologist and one of the first exponents of comparative psychology. He participated in debates that were key in the establishment of comparative psychology as a science, contributing with relevant concepts such as *Morgan's Canon* and *Emergent Evolution*.

### About His Life

Morgan was born in London, England (February 6, 1852), but soon moved to Weybridge with his family. During his childhood, he was described as remarkably curious, as reflected in his early readings of the philosopher, George Berkeley. He started studying at Brenchley, Kent, to later enter the Royal Grammar School in Guildford.

Although Morgan was not entirely convinced of his choice – which was strongly influenced by his father – his university studies began at the

Royal School of Mines in London in 1869 to become a mining engineer. As a result of excelling in his studies, he obtained a diploma in mining and metallurgy. However, his interests went further and broke down the geo-mathematical barriers, expanding his focus to the biological sciences and the scientific method.

Because of his studies on mathematics, Morgan was offered a position as a private tutor of a wealthy family, with whom he had the chance of traveling across North and South America, with experiences that would be later reflected in his work. As a consequence of his trip to America, Morgan decided to explore science beyond the field of physics and biological sciences. Motivated by Darwin's readings, the viability of reconciling philosophy and science began to be an interesting question for him. Consequently, on his return to the UK, he had the opportunity to study for a year under Thomas H. Huxley, a British biologist recognized for his fierce defense of Darwinian theory and evolutionism, who made multiple advances in zoology and compared anatomy. The support and influence of Huxley were transcendental for Morgan's incursion in biology and animal behavior.

In the midst of Morgan's growing career, in 1878 he married Emily Charlotte Maddock, Londoner with whom he had two children, being one of the few non-academic events in Morgan's life for which there is a record.

Between 1878 and 1884, he spent his time in South Africa as professor of different areas such

as physical sciences and literature at the Diocesan College in Rondebosch, Cape Town. Five years later and back in England, he became professor of zoology and geology at the University College of Bristol and stayed there for the rest of his academic career. In 1887, he was elected for the position of principal and in 1909 vice-chancellor. Subsequently, around 1910, he continued his work as professor of psychology and ethics, retiring in 1920 as Emeritus Professor of Psychology.

## Theoretical Contributions

### In Search for a Scientific Comparative Psychology

In the first half of the 1880s, Morgan was skeptical about the viability of a science of animal minds. In that time, the basis of the knowledge about mental processes was introspection; its conclusions could be checked through verbal verification, not possible with non-human animals. This was critical to Morgan given that “verification is that which makes science science” (Morgan 1885, p. 165). Therefore, comparative psychology would not become a science, in contrast to his proposal of an objective psychology (verifiable and occupied with the nervous system and the comparison of adjustive actions between species; Böhnert and Hilbert 2018). However, his positions about the scientific status of comparative psychology began to change. Now his critiques were oriented to move the field forward. For example, Morgan (1886) asserted that inferences about animals’ mental states in light on knowledge of human psychology achieved via introspection (also known as “ejective method”) could be an erroneous path since the extent of psychical differences between species is unknown. This would imply not considering anecdotes as scientific evidence, because much of them were biased, describing facts according to the observer’s interpretations.

Considering all this, a better option was focusing research on observable behavior under different circumstances, including learned, developmental, and phylogenetic contributions to such behavior and its biological basis. This implies

letting aside the speculation on the motives of the observed action. In this way, the ejective method should be kept at minimum while the discipline becomes more professional and scientific.

Morgan’s positions were opposed to his colleague, George Romanes, who thought that a science of animals’ mental life was possible and based part of his work on anecdotes and speculation. However, the exchange between both men made Morgan soften his positions even more. For example, in 1890, Morgan accepted the viability of a science of animals’ minds and showed more sympathy toward the ejective approach to comparative psychology (Fitzpatrick and Goodrich 2017). Romanes noticed that Morgan’s critiques were no longer directed to all the inferences on animal mental activities but to particular and concrete inferences. At this time, his taxonomy of psychological faculties defined certain concepts (reflex, instinct, and intelligence) in terms of non-observable variables, much like Romanes and away from his own previous definitions in the 1880s. The main disagreement at this time was if animals could be able to reason, to which Morgan objected.

A short time later, Morgan changed his positions again, this time away from Romanes. Morgan argued that carefully designed behavioral experiments with well-controlled variables could tell us about the psychological processes underlying observable behaviors, more than “thousands of anecdotes” (Morgan 1894, p. 291). In this way, questions about the reasoning capacities of animals – and other mental processes – would be subjected to experimental verification rather than just philosophical discussion.

Morgan also argued in favor of ecological validity and criticized Edward Thorndike’s experiments for being too artificial and not allowing the display of the natural abilities of animals. Interestingly, this would be a concern later in behavioral and cognitive sciences.

His calls for the adoption of experimental methods were influenced by the spirit of the time and his correspondence with his friend, Mann Jones. The adoption of this method would be to Morgan the hallmark of a maturing science.

## Emerging Evolution

According to Doat and Sartenaer (2014), Darwin's evolution theory brought with itself, at an implicit level, a naturalist philosophy committed to the idea that evolution occurs without leaps, gradually and through quantitative, not qualitative, changes. Given this, Thomas Huxley and other evolutionists wondered about the ways in which a purely quantitative process gives rise to differences between species, a qualitative aspect. From this question, it is possible to raise the existence of what the authors understand as "new naturalism," which indicates that evolution is a creative process that produces genuine novelties, in contrast to Darwinian naturalism, committed to a reductionist form of materialism that understood that the result of biological changes was already implicit in their conditions of appearance, being impossible to think of genuine novelties.

Within this new naturalism is framed Morgan's naturalism, which he called "Emerging Evolutionism." As can be deduced from its name, this vision is based on the concept of emergence – the idea that an emergent is determined by its conditions of appearance but is not reducible to them and, therefore, is unpredictable. The concept of "emergence" associated the idea that the process by which the emergent appears is continuous and discontinuous at the same time.

Following this logic, in a continuous process, genuine novelties emerge. Thus, naturalism could be thought of as a third way between Huxley's discontinuous evolution on the one hand and Darwin's gradualist vision on the other.

The concept of "emergency," in which this line of thinking is based, cannot be fully understood without the vision of a hierarchized world, where the top of this hierarchy is more complex than the bottom. In this sense, Morgan viewed the human species at the top, in contrast with Darwin's vision on evolution.

## Animal Intelligence

Another conceptual contribution present in Morgan's theory is the reformulation of the notion of "animal intelligence" (Fitzpatrick and Goodrich 2017). It arises from the dispute with George

Romanes, who proposed that the reason could explain individual differences produced by learning. On the contrary, Morgan's skepticism about this possibility was based on the idea that reason depends on language. Thus, for him there was no theoretical reason for attributing complex cognitive abilities to non-human animals.

According to Romanes, the capacity of learning on human animals necessarily involved a conceptual understanding of the world. For Morgan, learning involved consciousness, not reason. Animal behavior is therefore explainable by a process of trial and error, a learning that is not conceptual, but associative, which Morgan called "intelligence."

## Morgan's Canon

One of the author's best-known contributions has been "Morgan's Canon." It was originally presented in 1892 at the International Congress of Experimental Psychology in England and published first in *The Limits of Animal Intelligence* (Dixon 1892), where Dixon made a synopsis of Morgan's work. It was not published by Morgan himself until 1894 in his book *An Introduction to Comparative Psychology*. The Canon states: "in no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale" (Morgan 1894, p. 53).

This statement indicated that animal behavior should not be equated with human behavior if it can be explained by "simple processes." An example of his proposal can be seen in the behavioral observations that Morgan made about his dog, Tony. One day, the animal managed to open the door to the garden, which could be interpreted as a "high-level mental process." However, Morgan had previously observed and recorded Tony's behavior in attempting to open the gate, leading him to conclude that this insightful action was a gradual trial-and-error learning process. This anecdote reflects the basis of what would become the renowned Canon, inviting us to think about whether every behavior should always be explained in the most "basic" way possible before giving it "more advanced" attributes.

Nevertheless, it has been pointed out that this interpretation is a misreading of Morgan's postulate. Indeed, the homologation of this Canon with the law of parsimony or with a version of Ockham's razor taken to psychology would be major distortions of interpretation. Some discussions argue that conclusions Morgan intended to reach were not precisely those of "simpler explanations of behavior will be the most appropriate," but rather, and as he would later explain, his proposal would relate to superiority and inferiority in terms of how new or old the process is in the evolutionary development of psychological processes (Thomas 2019). Accordingly, Morgan emphasized: "in no case is an animal activity to be interpreted in terms of higher psychological processes, if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development" (Morgan 1903, p. 59). Because Morgan's first statement is the best known, and the later erratum went largely unnoticed in the literature, there are multiple interpretations of the actual meaning of Morgan's Canon.

## Morgan's Legacy

Morgan died on March 6, 1936, in Hastings, Sussex, England, at the age of 84. Until his death, he had made multiple contributions to fields related to animal cognition and behavior.

His best-known contribution, the Morgan's Canon, serves as an anchor for research on mechanisms at the base of animal and human behavior. For example, operant conditioning – a mechanism vastly conserved in evolution – explains a wide range of people's behavior, from creativity to personality, and even maladaptive behavior, based on the simple principle of learning by consequences.

In the context of the establishment of comparative psychology, the Canon, as well as debates about the feasibility of comparative psychology as a science and its own experimental work, helped to replace the somehow weak basis of comparative psychology for more solid grounds, leading it to become a rigorous scientific discipline.

## His Published Work

His work includes *Instinct* (1884); *Psychology in America* (1891); *The Limits of Animal Intelligence* (1892); *An Introduction to Comparative Psychology* (1894); *Mental Factors in Evolution* (1909); and *Emergent Evolution* (1923); among others.

### Crypsis

## Definition

Strategy of an organism that decreases its detectability and recognition by prey or predators.

## Introduction

Organisms with conspicuous patterns are more easily detected by their predators and/or prey, with consequences for their success when fleeing or preying, respectively (see ► [“Predator”](#) and ► [“Prey”](#) in this book). On the other hand, a perfectly cryptic or camouflaged organism represents one of the most remarkable exhibitions of how evolution by natural selection can mold and adapt species to its environment by increasing survival and reproductive success (Brakefield 2009) (See ► [“Adaptation”](#), ► [“Evolution”](#), and ► [“Natural Selection”](#) in this book). The word camouflage comes from the French word “camoufler” or the Italian word “camuffare” with the meanings “to disguise” or “to deceive”, respectively, yet the word “crypsis” comes from the Greek word “krypsis” and means “hiding” or “concealment”. Crypsis is a camouflage strategy that prevents the detection of the organism using it

(signal emitter) by an operator (signal receiver). A cryptic organism can have morphological and/or behavioral traits that make it difficult for the operator to detect it as a discrete entity or to locate its position (Ruxton 2009) (see ► [“Morphology”](#) in this book). There is experimental evidence demonstrating that camouflage can be adaptive in organisms even though it can incur costs (e.g., internal, external, indirect, design and plasticity costs), but to assess this the factors that affect the cost-benefit trade-off need to be evaluated (Ruxton et al. 2004).

Organisms can be camouflaged by their morphological similarity with the background, which is an example of background matching. Camouflage, however, can be even more efficient when behavior is involved, such as when a camouflaged organism remains still, like the thorny devil lizard (*Moloch horridus*), which has striking morphological camouflage that works only when the lizard is immobile (Alcock 2009) (Fig. 1), or when an animal, such as a chameleon or cephalopod rapidly changes its color pattern while in movement (see ► [“Color Change”](#) in this book). Some animals flatten their bodies to avoid being detected or use stealth by taking on appearance of objects that are uninteresting to the operator. This is known as masquerade and is a kind of camouflage by which an organism resembles an object that is inanimate or inedible to the operator, such as a twig, rock, leaf or bird dropping (Skelhorn et al. 2010). Since this strategy consists of not being recognized as potential prey or predator, and includes some aspects of the abiotic background, many cases of masquerade fall somewhere between crypsis and mimicry (Ruxton et al. 2004) (see ► [“Mimicry”](#) in this book). In this sense, the difference between the camouflage strategies of crypsis and masquerade is that crypsis prevents detection by the operator while masquerade is detected but prevents recognition.

The selective pressure on camouflage also selects behavioral traits of the emitters because the benefit can be maximized when the organism adjusts itself to a background (Edmunds 2008). This is a complex task because the operator can be sensible to alterations, and so the camouflaged organism must remain similar to a background

**Camouflage, Fig. 1** The thorny devil lizard (*Moloch horridus*) shows morphological similarity with the background (dead leaves) while it remains still. (Photo courtesy of © John Alcock)

that can be dynamic (Ruxton et al. 2004). The senses of the emitter are also important for camouflage. For example, the cuttlefish (*Sepia officinalis*) can imitate texture patterns of the background but not the colors, since this species cannot distinguish some wavelengths of light (Marshall and Messenger 1996).

Another important factor is that background, is operator dependent since different operators can cause selection for different combinations of camouflage traits that are performed by the emitters in a habitat (Ruxton et al. 2004). Therefore, camouflage is a function of the physical habitat, the sensory physiology of the operator and the camouflage traits of the emitter (Ruxton et al. 2004). Since camouflage can depend on background choice, it can differ for each different phenotype in a polymorphic species (Stevens and Ruxton 2018) (see ► “Polymorphic” in this book). This can lead to apostatic selection, which is a kind of frequency-dependent selection by which predators prey mainly on more common forms (morphs) and do not prey as much on more rare forms in a population, thus maintaining polymorphisms (Bond and Kamil 1998) (see ► “Frequency-Dependent Selection” in this book).

Organisms can use several strategies that are considered cryptic to avoid being detected, such as cryptic coloration (see ► “Cryptic Coloration” in this book), disruptive coloration (see ► “Disruptive Coloration” in this book), countershading

(see ► “Countershading” in this book), or decoration (see ► “Self-Decoration in Dolphins” in this book). These strategies are likely to be affected by behavior since it has a key role in camouflage (Stevens and Ruxton 2018), and thus they differ from other strategies, such as aposematism, for example, that facilitates an organism’s detection (see ► “Aposematism” in this book).

Camouflage has been mainly studied with regard to its visual aspect since humans are principally visually oriented organisms. Humans use camouflage to hunt (interspecific interactions) and as a social or military strategy (intraspecific interactions) to avoid being detected by enemies and to avoid being attacked or to facilitate attacking. A classic example of visual camouflage is the peppered moth (*Biston betularia*), a well-studied case that is due to the alterations observed in the color patterns of their wings as a result of pollution – a phenomenon known as industrial melanism. In other words, the frequency of dark forms (melanic) of this moth increased during the Industrial Revolution because pollution darkened their background (trees with lichen-covered bark). Three main components influenced this melanism and can be applied to other species that have evolved it: (1) the environment changed as a result of pollution and the camouflage of the “typical” type was impaired; (2) moth survival improved because a mutant phenotype provided protection from predatory birds that hunt these moths when they are resting on trees in this new environment;

(3) the mutant phenotype, specified by the dominant allele at the gene for color pattern, increased in frequency under the influence of natural selection, leading to the species exhibiting industrial melanism (Brakefield 2009). Furthermore, there is evidence demonstrating that predation by birds in different backgrounds acts as a selective agent on the characteristics of these moths (Brakefield 2009).

Despite being deeply studied for its visual aspect, camouflage is a strategy that can be widely applied to other senses and vary according to the sensory universe preponderant to each organism. There are suggestions of, and evidence for acoustic, chemical, electric, motion, and tactile camouflage.

### Acoustic Camouflage

Acoustic camouflage can be expected to be a widespread phenomenon for organisms to which hearing is an important sense. In acoustic camouflage the structure of an acoustic signal is modified

in such a way that its detection by predators or prey is more difficult, with evidence suggestive of a small number of organisms in some sensory systems (Ruxton 2009). Male fowls (*Gallus gallus*) and the great tit (*Parus major*), for example, are known to use alarm calls that reduce the ability of their predators to detect the emitter, while at the same time warn companions about a predation threat (Klump et al. 1986; Bayly and Evans 2003) (see ► “Alarm Calls” in this book). Nocturnal moths are likely using acoustic camouflage when they choose to stay on rough surfaces, because on smooth surfaces they would be found with greater ease by predatory bats due to difference in the strength of echoes from the moth and its surroundings (Clare and Holderied 2015) (Fig. 2). In the visual context, when an operator detects the existence of an object it also simultaneously obtains a significant information on the position of the emitter. With sound, however, the same is not necessarily the case, since an operator can detect an emitter in its surroundings without information on its specific location (Ruxton 2009).

#### Camouflage,

**Fig. 2** Different substrates where moths rest and can be acoustically camouflaged. Bark is the most difficult surface for echolocation by bats, while slate is easier. (Photo by © Clare and Holderied (2015) licensed under Creative Commons)

## Chemical Camouflage

There are many examples of chemical camouflage, mostly of which come from eusocial insects. Because of the inconsistency with which the term ‘chemical camouflage’ has been used within chemical ecology, and the confusion that has resulted, the terminology for this kind of camouflage was recently reviewed (von Beeren et al. 2012). The accepted terminology became: ‘chemical crypsis’ when an operator does not detect an emitter as a discrete entity (background matching), and no reaction is caused in the operator; ‘chemical masquerade’ when the operator detects the mimic but misidentifies it as an uninteresting entity (causing no reaction in the operator); and ‘chemical mimicry’ when an organism is detected as an interesting entity by the operator (causing a reaction in the operator) (von Beeren et al. 2012). On the other hand, chemical masquerade can also occur when an organism lacks odor, which is known for insects, mainly obligately parasitic species, including slave-making ants. Using this strategy, parasites and queens of slave-making ants can break into a host ant species’ nest without being attacked (Lenoir et al. 2001).

The moth caterpillar (*Biston robustum*) uses visual masquerade by being visually similar to the twigs of their host plants, and thus may avoid human or bird (mainly visually oriented) detection (Akino et al. 2004) (Fig. 3). However, this species also uses chemical crypsis, with their odor resembling those of their host plants, leading them to be ignored by potential predators that are chemically oriented, such as ants (Fig. 4). Furthermore, the diet of the moth caterpillar influences its appearance and its chemical odor. Akino et al. (2004) demonstrated that when the host plant of these caterpillars is changed, the caterpillars no longer visually look like the twigs of their previous host plant and they acquired the chemical odor of the new host plant on which they were placed. The same has been documented for treehoppers (*Guayaquila xiphias*), whose chemical crypsis allows them to attract predaceous bodyguards (ants) at reduced risk of falling prey themselves since they possess high chemical similarity to their host plant (Silveira et al. 2009). The

**Camouflage, Fig. 3** The moth caterpillar (*Biston robustum*) uses visual masquerade, being visually similar to the twigs of its host plants. (Republished with permission of Springer Nature, from © Akino et al. 2004)

filefish (*Oxymonacanthus longirostris*) feeds on coral and also shows a diet-induced chemical crypsis that decreases its detection by predatory cod (*Cephalopholis* spp.) (Brooker et al. 2015).

## Electric Camouflage

Electric camouflage, also known as bioelectric crypsis, occurs when an electric signal is modified in a way that makes the detection of the emitter more difficult for the operator. Such electric signals are only detected in water, due to its physical properties as a medium, and are used mainly by fish, despite reports of their use by a few amphibian species. They are also only efficient over short distances but can be used to detect organisms even if they are buried, unlike vision (Ruxton 2009).

The electrical discharges that some predatory electric fish use to find their prey do no contrast with lightning noise, and thus are useful for approaching prey without being detected (Hopkins 1973). In other words, these fish likely camouflage their electrical signals to hunt. It is well-known that the cuttlefish (*Sepia officinalis*) uses visual camouflage, but these cephalopods can also use bioelectric crypsis by using a behavioral freeze response to predator stimulus by flattening themselves, diminishing their breathing rate, and closing their orifices, leading to a reduction in their bioelectric fields which predators, such as sharks, can detect (Bedore et al. 2015) (Fig. 5).

**Camouflage, Fig. 4** The moth caterpillar (*Biston robustum*) uses chemical crypsis, with its odor resembling that of their host plants. (Republished with permission of Springer Nature, from © Akino et al. 2004)

**Camouflage, Fig. 5** The cuttlefish (*Sepia officinalis*) can use bioelectric crypsis in response to a looming predator. Both the frequency and amplitude of body movements and

bioelectric cues are reduced during their freeze response. (Republished with permission of The Royal Society, from © Bedore et al. 2015)

### Motion Camouflage

Even though stillness can be essential for camouflage to work for an organism, the presence of

movement can be fundamental for another kind of crypsis: motion camouflage. Motion camouflage can be achieved if an organism's movement occurs in a way that decreases the probability of

the organism's detection (Stevens and Merilaita 2009). For example, some insects, such as males of the Australian emperor dragonfly (*Hemianax papuensis*) use motion camouflage to disguise themselves as stationary when in fact they are performing territorial aerial maneuvers (Mizutani et al. 2003) (Fig. 6).

Despite looking like old leaves, the stick insect (*Extatosoma tiaratum*) pays attention to environmental cues and adjusts its behavior accordingly, such as using a swaying behavior in windy conditions to reduce the ease with which it can be distinguished visually from surrounding plants (Bian et al. 2016). Its movements are consistent in frequency with the movement of moving foliage, and thus can represent motion camouflage or masquerade, or a combination of both (Bian et al. 2016).

### Tactile Camouflage

Some organisms use touch to communicate or find prey, and thus this signal can be exploited to hamper detectability as a camouflage strategy.

For example, due to a mutualistic association with certain sponges (*Mycale adhaerens* and *Myxilla incrustans*), scallops (*Chlamys hastata* and *C. rubida*) use tactile camouflage against starfish predators (*Evasterias troschelii*) and escape because their sponge-cover drastically reduces the adhesive ability of tube-feet by altering their surface texture, thereby significantly reducing the probability of their capture (Bloom 1975).

A chemical-tactile camouflage seems to occur when the blue mussel (*Mytilus edulis*) is fouled by its hydrozoan parasite (*Laomedea flexuosa*), because the mussel's predator, the shore crab (*Carcinus maenas*), retreats from mussels on first contact when they are thusly fouled (Enderlein et al. 2003) (Fig. 7). Theoretical models suggest that the foot morphology of some dinosaurs caused their steps to produce seismic waves that could be detected through mechanoreceptors, and thus could be camouflaged by seismic wave motion camouflage, which would reduce the probability of detection by ambush predators or by prey (Blanco et al. 2018) (see ► “[Mechanoreceptors](#)” in this book).

**Camouflage, Fig. 6** An interaction between two males of the Australian emperor dragonfly (*Hemianax papuensis*) where the emitter (smaller dots behind) uses motion camouflage to disguise itself as stationary from the operator

(bigger dots in the front), when in fact they are performing territorial aerial maneuvers. (Republished with permission of Springer Nature, from © Mizutani et al. 2003)

**Camouflage, Fig. 7** A chemical-tactile camouflage seems to occur when the blue mussel (*Mytilus edulis*) is fouled by its hydrozoan parasite (*Laomedea flexuosa*). The mussel predator, the shore crab (*Carcinus maenas*), prefers

to feed on mussels without the epibiont (arrow points at significantly preferred prey). (Republished with permission of Elsevier, from © Enderlein et al. 2003)

## Strategies Against Camouflage

Predators and prey possess their own strategies against camouflage, but these have been mainly studied in predators. Predation can maintain, or prevent the origin of, certain color patterns and polymorphisms of prey due to a variety of biological phenomena including perceptual processes, such as search images (see ► [“Search Image”](#) in this book), optimal foraging (see ► [“Optimal Foraging Theory”](#) in this book), and learning (see ► [“Learning”](#) in this book) (Endler 1988). This is because the majority of species are preyed upon by more than one species that possess different foraging strategies and perception and learning abilities, which influences the forms (morphs) that are selected (Endler 1988). Thus, some factors of the predatory species influence, as for example their cognitive and sensory abilities, food choice, timing of predation, among others, as well as some anti-predator factors such as camouflage, background choice and other conditions and defenses used against the predators after it is detected as for example running away, mechanical defenses, and distastefulness to the predators (Endler 1988).

## Conclusion

Camouflage is a strategy of an organism that decreases its detectability and recognition by prey or predators, and is dependent on behavior, background, environmental conditions, and the cognition and senses of the operator and the emitters. Although widely studied from the visual perspective, there is evidence that camouflage can also be acoustic, chemical, electric, motion, and tactile, with some organisms being able to exploit more than one kind of camouflage depending on the cognition of different operators. Nonetheless, for these other senses, there exists, in general, less evidence. This lack of evidence does not necessarily mean that these are rare cases in nature, but instead that there have been fewer studies involving senses other than vision. Furthermore, what has been learned about visual camouflage can also be studied and applied to

other senses if the characteristics of each signal are respected. There remain open questions regarding the costs performing camouflage, as well as why some organisms are selected for some kinds of camouflage and others are not, and for another strategy instead, such as mimicry or aposematism, for example. It is known that operator influences, and some characteristics of individuals can be selected due to different pressures from different operators. To elucidate the morphological and behavioral constraints to the evolution of cryptic traits, comparative phylogenetic methods seem to hold the most promise.

## Canalization

Bhumika

Department of Zoology, Sunderwati Mahila College, Tilka Manjhi Bhagalpur University, Bhagalpur, India  
Genetics Laboratory, Department of Zoology, Institute of Science, Banaras Hindu University, Varanasi, India

## Definition

Canalization refers to reduced phenotypic variability in traits against any environmental or genetic perturbations.

## Introduction

Canalization refers to the robustness in the phenotypic traits in response to any environmental perturbations (environmental canalization) or genetic changes (genetic canalization). The concept of canalization was first introduced by Conrad Hal Waddington (1942). He described it as “wild type of an organism, the form less variable in appearance than the majority of the mutant races” (Waddington 1942, p. 563). Canalized traits show near optimal fitness value and are less phenotypically variant as opposed to traits showing phenotypic plasticity. The evolutionary role of canalization has been widely postulated by several researchers (Siegal and Bergman 2002; Flatt 2005; Debat and David 2001) and over the years the conceptual understanding of canalization has been revisited and modified repeatedly.

The idea of canalization was also suggested independently by Schmalhausen (1949). He proposed that stabilizing selection, a form of natural selection, plays a prominent role in maintaining the canalized state of a trait. A trait undergoing a stabilizing selection shows an average or intermediate value and represents the equilibrium state of a particular phenotype in a population. According to Schmalhausen, stabilizing selection tends to buffer the developmental pathways against any genetic or environmental perturbation and thus maintains the traits in a canalized state. However, it has also been now reported that the buffering mechanisms maintained by stabilizing selection can be disrupted if directional selection comes into play (Groth et al. 2018). If such a scenario occurs, there may be decanalization of traits or reduction in canalization of traits occurs.

## Canalization and Cryptic Variations

Reduction in phenotypic variation usually implies less evolutionary potentiality and reduced adaptability of traits in face of changing environmental conditions. Although canalization reduces phenotypic variation and is known to impede adaptation in the short term, it can be a “capacitor of evolutionary change” (Gibson and Reed 2008, p. 2),

when the process is followed by decanalization. The process of canalization leads to the buildup of hidden or cryptic genetic variation. The accumulated hidden genetic variation which remains invisible in the population becomes visible as a phenotypic variation when an individual encounters novel environmental conditions or if new genetic mutations occur in an individual. In the process of canalization, i.e., during the buffering of developmental pathways, if there is accumulation of new mutations that are suppressed during the process, then a new selection process can lead to potential evolutionary divergence in an organism.

As an example, in *Drosophila melanogaster* the Hsp90 heat-shock protein encoded by *Hsp83* locus acts as a capacitor for morphological evolutionary response (Rutherford and Lindquist 1998). When Hsp90 was mutated or impaired using inhibitors, varied phenotypic responses were observed in *Drosophila* flies, like developmental abnormalities in body parts, changes in wing venation and shape, and bristle duplication. Such results indicate the involvement of Hsp90 protein in promoting the canalization process by suppressing the expressivity of variations associated with the morphogenetic pathways. The uncovering of hidden genetic variants by impairment of Hsp90 allows selection to act upon the variants, thus paving the path for occurrence of morphological radiations. Similar results were obtained in *Arabidopsis thaliana*, where Hsp90 was found to buffer against genetic and environmental perturbations, and reduction in its activity resulted in enhancement of genetic variations (Queitsch et al. 2002).

## Canalization and Genetic Assimilation

Genetic assimilation refers to the process by which a phenotypic plastic character expressed in response to any environmental change gets constitutively expressed as canalized trait even in the absence of the environmental cue which evoked it (Crispo 2007). The process of genetic assimilation promotes evolutionary divergence and speciation through the establishment of a new canalized trait which tends to be more

adaptive in nature. The fixation or canalization of traits during the process of genetic assimilation occurs due to selection acting on the changes occurring in the genetic regulation of morphogenetic pathways in response to an environmental stimulus. The phenomenon of genetic assimilation was demonstrated by Waddington (1953) for cross-veinless (*cvl*) wing phenotype of *Drosophila* which possesses defects in venation patterns. When artificial stress in the form of temperature was applied in fruit flies at early developmental stages, Waddington found the occurrence of *cvl* phenotypes. When these variants were artificially selected as parents for the next generation, an increase in the frequency of the *cvl* phenotype was observed and after a number of generations he found the occurrence of the *cvl* phenotype even without heat shock treatment. Thus, Waddington was able to genetically assimilate the environmentally induced *cvl* phenotype in *Drosophila* in a canalized state.

## Conclusion

Research to date has elucidated the role of canalization in potential evolutionary consequences. In the long term, the release of accumulated cryptic genetic variants under specific decanalizing environmental or genetic conditions paves the way for phenotypic diversification in a population, thereby increasing its evolvability. However, the consensus regarding the origin and mechanisms involved behind the phenomenon of canalization still remains elusive. This is largely due to presence of gaps in the studies pertaining to measurement of canalization as well as due to ambiguity in different hypotheses provided by researchers. Waddington (1957) mostly considered canalization as an intrinsic property of a genotype that shows less variation than other genotypes. He did not take into account the role of any mechanism or process behind the phenomenon and simply considered it as the quality of an organism. The hypothesis that canalization has an adaptive role and aids in the process of evolution has now been proposed and still the molecular mechanisms involved in the process of canalization need to be elucidated (Stearns 2002). The regulatory networks involved in buffering

against environmental and genetic perturbations need to be identified. Unraveling the genetic and molecular mechanisms underlying canalization will be the focus of future research in this area.

## Candidate Gene

Prerna Giri and Bhagyalaxmi Mohapatra  
Cytogenetics Laboratory, Department of Zoology,  
Institute of Science, Banaras Hindu University,  
Varanasi, UP, India

## Synonyms

Genome-wide association studies; Positional candidate gene approach; Putative candidate gene

## Definition

A candidate gene is gene which is presumed to be associated with a particular disease or a phenotypic trait, whose biological function(s) is derived either directly or indirectly from other studies including animal model studies with other species (using comparative genomic studies), genome-wide association studies (GWAS), classical map-based positional cloning method, and a more recent next-generation sequencing (NGS) methods.

## Introduction

Identification of certain genes with known function causal for diseases, (e.g., *MSH2* and *MLH1* causing colon carcinoma) evolved the candidate gene approach in disease biology. Further candidate genes were discovered by either direct screening of genes in a biochemical pathway with known related functions associated with the pathogenesis of the disease (PKU, AKU), or indirectly derived from the animal model studies (e.g., *DFBN3* deafness gene identified using mouse

shaker-2 mutants) (Fig. 1). Lately, studies involving candidate genes have been used as an important aspect of genetic association studies for identification of risk associated with a particular genetic disorder. The candidate gene approach begins with the selection of a probable candidate gene, based on its role in the development of disease phenotype, which is followed by identification of polymorphisms and finally the variants are assessed for disease association. Candidate genes are generally the genes with known biological significance directly or indirectly regulating the development processes of the investigated traits, which could be confirmed by evaluating the effects of causative gene variants in an association analysis (Zhu and Zhao 2007). Candidate gene approach is population based and hypothesis driven. This is mostly based on case-control study. Due to the presence of great variability among organisms it is often difficult to distinguish SNPs from candidate genes. Currently, availability of great amount of genetic information deciphered through online databases has enabled researchers to explore the existing data and in silico tools deeply for identification of new candidate genes. A number of other methods were used to identify genes linked to disease before the candidate gene approach was fully developed. These methods are based on genetic linkage and positional cloning.

The candidate gene approach is used widely not only in animal genetics but also in plant genetics for characterization and cloning of Mendelian as well as Quantitative Trait Loci (QTLs). It constitutes a complementary strategy to map-based cloning and insertional mutagenesis. In plant genetics, the candidate gene identification is performed by looking for map co-segregation between candidate genes and loci affecting the trait. Statistical association analyses between molecular polymorphisms of the candidate gene and variation in the trait of interest have also been carried out in a few studies (Pflieger et al. 2001).

## How to Carry Out a Candidate Gene Study?

The first and the most important step in carrying out a candidate gene study is selecting a suitable

**Candidate Gene, Fig. 1** The candidate gene identification approach

gene that may plausibly play an important role in the diseased phenotype. The next step is selecting a DNA polymorphism. It is very important to decide which polymorphism would be most useful in an association study. The existing gene variants must be identified and it should be determined that which of these gene variants result in proteins with altered functions. The genetic variants can be identified through sequencing. Polymorphisms can be of much importance in studying complex disorders for which many potential candidate genes exist. The final step in carrying out a candidate gene study is to test the candidate gene in a random group of disease samples (cases) and healthy individuals (controls). But the case control study may result in fallacious association if the controls are not properly matched to the cases with respect to ethnicity and other factors which contribute to the genetic composition of an individual.

### Role of Candidate Gene Approaches in Complex Genetic Traits

The candidate gene approach is the study of genetic influences on a complex genetic trait by generating hypotheses and identifying candidate gene that may play a role in the etiology of disease and variant identification in genes that might either cause a change in the protein or its expression (Tabor et al. 2002). A candidate gene study is generally conducted in a population-based sample of affected and unaffected individuals, i.e., the case control study as discussed in previous paragraph also. A candidate gene study takes advantage of statistical efficiency of association analysis of complex diseases and the understanding of phenotype, tissues, genes, and proteins that are likely to be involved in disease. Association in candidate-gene study can be defined as a statistical dependence between two or more events which is greatly influenced by the

characteristics of the study including size of the population studied and number of variables. Candidate gene can be very useful in exploring the potential causal pathways between genetic determinants and complex diseases. There are mainly two approaches for genetic dissections of complex and quantitative traits, i.e., genome-wide scanning (GWAS) and candidate gene approach.

Digital Candidate Gene Approach (DigiCGA)

DigiCGA is also known as in silico candidate gene approach or computer-facilitated candidate gene approach. It is a web-based candidate gene identification approach that objectively extracts filter, (re)assembles or reanalyzes all possible available resources derived from public web databases mainly in accordance with the principles of biological ontology and complex statistical methods for computational identification of potential candidate gene of specific interest (Zhu and Zhao 2007). A number of online tools are available for prioritizing candidate genes such as Endeavour, Pocus, G2d, Suspects, etc. (Table 1).

Limitations of Candidate Gene Approach

The findings of candidate genes are not easily reproducible in subsequent studies because of population stratification. Therefore the design of study should be very specific. Since it is a hypothesis-driven approach, the findings of candidate genes are biased as compared to anonymous approaches such as linkage analysis, genome-wide association studies (GWAS), microarrays, etc. The restricted knowledge can result in “information bottle-neck.” Hypothesis-driven genetic approaches are less likely to yield result than other approaches (linkage analysis, GWAS, etc.), which uses markers throughout the genome and do not depend on the ability to select a plausible candidate.

Conclusion

Candidate gene approach has been a pioneer in the field of genetic epidemiology, identifying risk alleles and their association with clinical traits. Candidate genes are related to a particular disease or condition and can be identified either on the basis of position or function. A positional candidate gene is located in a chromosomal region suspected of being linked to a disease and functional candidate gene is a gene encoding a product associated with the disease. Candidate gene analysis is usually the indispensable procedure for subsequent positional cloning of QTLs (Qualitative Trait Loci) controlling the major genetic variation of interested traits after initial genome scans. Candidate gene studies can utilize the data made available through comparative genomic studies from other species, genome-wide association studies, whole genome gene expression profiling, next-generation DNA and RNA sequencing, CHIP-seq to unravel a multitude of susceptible disease associations. The next-generation data and candidate gene approach can give rich dividends in terms of elucidation of complex disease mechanisms, better prognosis and diagnosis of patients in a short time, and an efficient way (Patnala et al. 2013).

 Thinking Dog Center, City University of New  
 York, New York, NY, USA

## Synonyms

[Dog behavior](#); [Dog cognition](#); [Dog intelligence](#)

## Definition

The study of the dog's mind. The process by which dogs acquire, process, and store information and conceptual skills that inform behavior, including sensing, perceiving, learning, remembering, and reasoning.

## Introduction

The species *Canis lupus* consists of two carnivores, wolves (*Canis lupus*), and a subspecies,

dogs (*Canis lupus familiaris*). Mitochondrial DNA indicates that dogs and modern-day wolves began to diverge from a common ancestor around 100,000 years ago with true domestication beginning approximately 14,000 years ago (for a review see Galibert et al. 2011). However, it is important to highlight that the place(s) of the dog's domestication event(s) and the process of how the domestication event(s) occurred remain unclear and contested.

Historically, dogs have been used as study subjects and model organisms in studies of psychological and biomedical research. Despite being the first domesticated animal, only recently have researchers recognized the unique role dogs occupy in our society (Bensky et al. 2013). In the last 30 years, the study of canine cognition has experienced a substantial boom. The number of journal articles on canine cognition and behavior has increased sixfold, from 218 papers (1993–2005) to 1307 papers (2006–2018), and increasing in trend since 2005 (Massimo et al. 2020). From these studies, scientists have discovered various cognitive abilities, many specifically related to understanding human social behavior, that make dogs a unique study species (Miklósi et al. 2003). Below, we highlight literature focusing on three main topics, presenting examples of canine: (1) perception, (2) non-social cognition, and (3) social cognition.

## Perception

Before delving into what is known about canine perception, it is important to note that dogs, arguably, represent the most morphologically diverse species on the planet. There is immense systematic variation between breeds, including size, height, facial morphology, and more. Most studies of dogs cannot possibly begin to provide a representative sample of all dog breeds, dog groups, morphological types, etc. Therefore, it is important to consider this limitation when generalizing results of perception to dogs as a whole.

Perception represents an individual's sensory experience of the world, specifically the process of identifying, organizing, and interpreting sensory stimuli through smell, sight, sound, touch,

and taste. The development of dog senses varies by modality. At birth, dog eyes and ear canals are functionally closed (for an overview of sensory development in dogs, see Lord 2013). Functional olfaction begins around 8–13 days, coinciding with the opening of the eyes. Visual forms are perceived around 25 days of age, and visually guided behavior begins at 4 weeks of age (Scott and Fuller 1965). Around this time, puppies begin to respond to sound, coordinated walking occurs, and environmental investigation begins (Lord 2013; Scott and Fuller 1965).

### Visual Perception

The majority of studies, 74%, evaluating canine cognition has presented subjects with visually based paradigms (Bensky et al. 2013). While few foundational assessments of dog vision and perception exist, many plagued by small sample sizes, research into more cognitively complex conceptions like visual discrimination, processing precedence, and face-processing has been conducted. Most commonly, the visual discrimination abilities of domestic dogs have been evaluated via object choice discrimination tasks. These studies have found that dogs can easily learn to discriminate between objects varying in color, shape, size, and quantity (for a review please see Byosiére et al. 2017). Not only can dogs discriminate between objects, but they are also adept at visually processing both humans and conspecific faces and discriminating between emotional facial expressions.

Certain similarities and differences exist when comparing dog and human visual perception. Like humans, dogs demonstrate a left gaze bias, but only when presented with upright human faces (Guo et al. 2009). Additionally, fMRI research indicates activation in brain regions responsible for face processing in humans, such as the temporal lobe and the medial and lateral frontal cortex, also appears to be associated with face processing in dogs (Cuaya et al. 2016). However, differences between human and dog visual perception have also been observed. Recently, studies of canine visual perception research have focused on evaluating how visual information is processed, interpreted, and modified, post-retinally, through studies of illusion susceptibility (Byosiére et al.

2017). These studies highlight that dogs often do not demonstrate humanlike susceptibility to certain geometric visual illusions, but rather demonstrate null or reversed illusion susceptibility. Taken together, these findings indicate that while there are parallels between dog and human visual perception, there are also differences that are important to consider.

### Olfactory Perception

Dogs are perhaps best known for their superior sense of smell. Yet, an immense gap in canine olfaction research exists (for a review of olfaction in dogs, see Gadbois and Reeve 2014). While the majority of research on canine olfaction has been conducted at either the cellular or behavioral level, few studies have evaluated olfactory perception at a cognitive level. As dogs, and their noses, are critical in applied fields, such as scent detection, understanding how olfaction and cognition interact has broad and far-reaching implications.

In comparison with a mere six million olfactory receptors in the human nose, the dog's nose is highly specialized. Dogs not only have 300 million olfactory receptors in their nose but also have a secondary olfactory organ, the vomeronasal organ. Dogs can follow scent trails, discriminate between different human individuals (including identical twins), be trained to assign novel odors to a known category, and form a representation of the objects they smell (for a brief review of olfaction and cognition in dogs, see Lea and Osthaus 2018). Preliminary evidence also suggests that dogs may demonstrate self-recognition in a modified olfactory version of the infamous mirror-self recognition test. Dogs were found to spend more time investigating odors of themselves compared to odors of themselves that were altered, indicative of the dog's recognition of their own odor (Horowitz 2017). While interesting, the question remains whether this modified olfactory test, while perhaps more ecologically valid in olfactory dominant animals like dogs, does, in fact, represent an analogous assessment of the mirror-self recognition test.

### Auditory Perception

Auditory perception, in general, is reliant on the successful transduction of sound waves into

electrical signals, the refinement and filtering of specific sounds, and the interpretation of those sounds. Dogs can hear sounds 400 m away, four times farther than humans, and are most sensitive to sounds that fall within the frequency range of 200–15,000 Hz (for a review of auditory perception in dogs compared to humans, see Barber et al. 2020). Studies of auditory perception in dogs suggest they can distinguish natural from artificial sounds and, like olfactory perception, can categorize novel sounds into known categories.

In social contexts, dogs can discriminate human spoken words based on their phonetic composition, doing so spontaneously for the same phonemes across different speakers (e.g., Root-Gutteridge et al. 2019). Additionally, there is evidence for the cocktail effect in dogs. A recent set of experiments suggests that dogs attend to their name when presented among background noise or equal or louder intensity (Mallikarjun et al. 2019). Moreover, dogs were able to recognize their name when spoken by an unfamiliar human via a loudspeaker.

While limited, due to smaller or single sample size, more complex examples of auditory cognition have been observed. Preliminary evidence suggests that certain dogs may demonstrate syntactic understanding. A single subject, Sofia, was able to generalize her behavior flexibly when presented with object-action requests. Additionally, dogs like Chaser (1022 words) and Rico (200 words) highlight that dogs can recall and recognize an exceptionally large number of proper-noun names.

## Non-Social Cognition

Non-social cognition, also referred to as physical cognition, considers how subjects perceive and respond to physical objects or stimuli within their environment. Compared to studies of social cognition, fewer studies have investigated non-social cognition (Bensky et al. 2013). Regardless, a substantial body of literature exists, specifically on topics such as canine learning, memory, object permanence, and means-end reasoning.

## Learning

Learning, which includes both classical and operant conditioning, involves the formation of an association between a stimulus and an outcome. Ivan Pavlov famously used dogs in his seminal work leading to the discovery of classical conditioning. Through surgical modification of the dogs' salivary glands, he observed that dogs were salivating when food was present (unconditioned response) but, at times, also when food was not present. Through a series of controlled experiments, Pavlov paired food (unconditioned stimulus) with a nonfood stimulus (conditioned stimulus), such as lights, sounds, and objects. After repeated pairings of the unconditioned and the conditioned stimuli, the dogs began to salivate in the presence of the conditioned stimulus alone (conditioned response). Since Pavlov's noteworthy work with dogs, these classical conditioning principles have been observed across canid species.

Through operant conditioning, also known as instrumental conditioning, behaviors are modified via their associations with positive or negative consequences. These principles are widely used in both canine cognition paradigms, for example, discrimination tasks, and applied fields, such as in the training of scent detection dogs. Frank (1980) claimed that there were differences in associative learning between dogs and wolves, with dogs being more capable of completing operant learning tasks than wolves. However, this generalization has not stood the test of time, and replication and the differences observed may well have been due to differences in rearing conditions. Thus, it is unlikely that operant learning capacities in dogs are in any way unusual when compared to other canids.

Once a dog has learned an association between a stimulus and an outcome, they may have difficulty suppressing the learned response. This has been demonstrated through the use of reversal learning tasks, in which dogs first make an association between an object and a reward in a two-choice operant learning task. When the conditions are reversed, and the unrewarded object becomes the rewarded object, dogs consistently take longer to make this new association. This outcome holds

true even when dogs are visually cued about the new location of the reward (Ashton and De Lillo 2011).

## Memory

The majority of canine memory research to date has focused on working memory. Working memory is adaptive and essential for animals, allowing them to solve problems and adjust to changes in the environment. In dogs, as in other species, performance on working memory tasks decreases as time between the initial presentation and recall increases. For example, when dogs observed an object hidden in one of four locations, they were able to successfully identify the location with 80% accuracy after 10 s and with 50% accuracy after 240 s (Fiset et al. 2003). Recently, an odor span test was used to assess canine working memory with scents, revealing that the 6 dogs studied were able to recall and discriminate between 72 odors with high accuracy (79% or higher) over a short period of time (Krichbaum et al. 2020). Furthermore, they were able to correctly identify a novel odor when up to eight intervening odors were presented, indicating that eight might be the working memory capacity for memory in dogs (for comparison, the working memory capacity in humans is seven).

Some, but few, studies have evaluated episodic memory in dogs. Episodic memory involves conscious recollection of personally lived past events, specifically the “what,” “where,” and “when” of one’s past experiences. To evaluate this in dogs, Kaminski et al. (2008) gave two dogs, Betsy and Rico, a chance to view two separate rooms with various objects located within them. The dogs were then asked to retrieve one of the objects. Rico seemed to vary his search pattern based on previous knowledge of the object’s location, indicating that dogs might possess the capacity to remember the “what” of past events. However, Betsy’s performance was less convincing as she carried out the same search pattern during each trial, regardless of the objects’ location. Overall, more research into canine episodic memory is needed before broad generalizations can be made.

Like many species, dogs demonstrate cognitive impairments associated with both aging and

dementia. As such, dogs have become a model species in the study of cognitive deficiencies in humans. Specifically, studies on canine cognitive dysfunction in dogs have supplemented our understanding of Alzheimer’s disease (Bensky et al. 2013). Memory and learning studies have been employed to both diagnose and further our understanding of canine cognitive dysfunction. For example, Adams (2000) used a delayed non-matching to position (DNMP) paradigm to both compare the cognitive abilities of young (1–3 years old) and aged dogs (8–12 years old). The authors found that aged dogs demonstrated impaired spatial learning and spatial working memory capacities when compared to young dogs. Furthermore, severely cognitively impaired dogs often failed to reach the criterion during the training phase, whereas slightly impaired and unimpaired aged dogs did not. Consequently, the DNMP paradigm can be used as a tool to diagnose canine cognitive dysfunction.

## Object Permanence

Initially set forth by Piaget, studies of object permanence offer the opportunity to evaluate an individual’s ability to understand that objects will continue to exist when they cannot be sensed. Typically in these tasks, an object is hidden in an opaque container (the displacement device) and then placed into or behind an occluder. Without the subject’s knowledge, the object of interest is then taken out of the displacement device and left in or behind the occluder. The subject, who is watching this procedure unfold, is then shown the displacement device, which is now empty. The theoretical mental process of understanding this task suggests that subjects must not only store and update information but also utilize a mental model to construct an internal map of where the object may be located.

Original assessments of object permanence in dogs were consistent with the conclusion that dogs could perform at the highest level of Piaget’s sensorimotor phase of development (Stage 6), solving both visible and invisible displacement tasks (Gagnon and Doré 1994). However, as more refined controls were added to the experimental paradigm, the results have become less

convincing. In follow-up studies, these authors suggest that within the task there is a theoretical distinction between the animal's representational ability to recognize and recall information. Recalling the object, rather than recognizing a cue association, suggests an animal possesses Stage 6 problem-solving abilities. More recent results conducted in dogs suggest that recall does not guide problem-solving in invisible placement tasks, and thus dogs likely demonstrate Stage 5 capacities at most.

More recently, Fiset and LeBlanc (2007) assessed how dogs use visual cues during invisible displacement tests. The authors found additional evidence for the conclusion that dogs demonstrate an understanding of visible displacement but not invisible displacement. In line with other studies of object permanence in dogs, the authors observed that dogs typically searched in patterns consistent with an adjacency rule, relying on locations nearest to the displacement device. Additionally, dogs used the experimenter as a local landmark when the displacement device was moved to a location close to the experimenter. Overall, the evidence suggests that dogs do not make inferences about an object's location during invisible displacement tasks and thus do not demonstrate the capacity for Stage 6 representational abilities. However, considering the mixed results, it does seem as though dogs can easily adapt and spontaneously employ a variety of strategies to complete the task.

### Means-End Reasoning

The lives of both humans and animals are riddled with everyday problems that need to be solved. Many of these are in fact novel problems that an individual may have not yet experienced. Means-end reasoning has been suggested to represent the way by which individuals get from a problem state to a desired goal state. Frequently, means-end understanding has been tested using a string-pulling task paradigm, in which a subject is presented with two string options. One string option has the desired object attached to it, and the other has no object attached. A barrier blocks direct access to the ends of both strings (i.e., where the reward is attached). If a subject identifies the

desired object can only be obtained by pulling the string, then they should be able to succeed on the novel task spontaneously. However, if the means to an end is obtained via repeated exposure and associative learning, then the individual does not demonstrate this ability.

To date, most studies of means-end reasoning in dogs indicate that dogs cannot successfully perform the task. While dogs can learn how to obtain out-of-reach desired rewards by pulling the string, they fail to do so spontaneously in a variety of experimental conditions, where ropes are crossed, straight on, or parallel. Much of this seems to be due to proximity errors (Osthaus et al. 2005; Range et al. 2011a) and may relate to confounds associated with inhibitory control. However, Range et al. (2011a) observed that dogs were able to solve means-end tasks when a board adaptation of the paradigm was used, called the "on-off problem." When two identical rewards were presented out of reach behind a fence, one lying on a board and the other lying next to a second board, dogs spontaneously demonstrated an ability to pull the correct board (the one with the food lying on top). Thus, depending on the paradigm, dogs can solve the means-end task successfully and spontaneously.

## Social Cognition

Considering their unique relationship with humans, dogs provide an interesting and exclusive model for understanding domestication and evolutionary processes. Dogs are particularly sensitive to human-given social cues and social learning (Hare and Tomasello 1999; Miklósi et al. 2003). Therefore, it is perhaps not surprising that more than half (54.7%) of the studies of canine cognition have specifically focused on social cognition (Bensky et al. 2013).

### Following Human Social Cues

Perhaps contributing to the surge in recent studies of canine cognition, numerous studies have found that dogs are uniquely attentive to human-given communicative cues. Compared to other non-human species, including our closest living

ancestors, the great apes, dogs are extremely adept at locating hidden food/toy when indicated via a human-given gesture (for a review pointing comprehension in dogs, see Kaminski and Nitzschner 2013)

Most of the studies investigating the canine response to human social cues have implemented an object-choice discrimination task. In this paradigm, a container is baited out of the subject's view. The experimenter then presents the dog with multiple containers (only one of which has food/toy inside) and provides a social cue, such as pointing, towards the target container. The dog is then allowed to select one of the containers. While many variations of cueing exist, there is overwhelming evidence that dogs perform significantly above chance when presented with a pointing cue, regardless of whether the point is proximal (less than 20 cm away from the cup) or momentary (cue is removed before the dog is released to make a choice). Dogs are also able to follow more subtle human-given cues, such as gazing in the direction of the target container (Kaminski and Nitzschner 2013). However, their performance is generally less proficient than following pointing cues, as some studies note at chance or below chance performance (for a review see Reid 2009).

Much contention exists about how this unique attentiveness to human-given social cues developed. It has been hypothesized that dogs' ability to make use of human social signals may have resulted from selection pressures during domestication. This conclusion is further supported by the fact that dogs outperform wolves (their closest relative) and chimpanzees (humans' closest relative) on gesture-assisted object choice discrimination tasks (Kaminski and Nitzschner 2013). Some researchers have found that puppies as young as 6 weeks old can follow human pointing cues in these tasks, thereby suggesting a possible genetic predisposition (for a review see Wynne 2016). However, other studies have found opposing conclusions, where puppies do not perform as well as their adult counterparts, suggesting that the comprehension of human communicative pointing cues improves with age (Dorey et al. 2010). Regardless of how this ability develops, at both

the proximate and ultimate level, there is substantial evidence to suggest that dogs are highly adept at following human-given social cues.

### Attention to Attention

Attention represents the cognitive process by which individuals process and respond to specifically relevant details within their environment while simultaneously ignoring other perceivable information. As dogs have coevolved with humans, they excel in paying attention to human communicative cues, behaviors, and vocalizations. Studies of attention in dogs have largely focused on perception or social attention to human-given communicative cues (discussed above). However, some additional studies have investigated dog's attention to both conspecific and human attentional states, both of which warrant discussion.

Inferential evidence of perspective-taking abilities in dogs can be taken from studies employing different theoretical designs. For example, Virányi et al. (2004) observed that dogs were more likely to take forbidden food when experimenters were not looking at them. Dogs also preferentially beg for food from individuals who can see them suggesting that dogs can differentiate between human attentional states. Observational research suggests that dogs are also able to take the perspective of their conspecifics. During dyadic social play, dogs have been found to display visual play signals almost exclusively towards individuals within visual view (Byosiére et al. 2015). Moreover, attention-getting behaviors, such as barks, were nearly always used when a play partner was not visually attentive to the signaler, and stronger attention-getters were used depending on the degree of inattentiveness of the play partner. These findings suggest that dogs are not only able to attend to others, but seemingly behave flexibly, matching their behaviors to the inattentiveness to their conspecific play partners.

While dogs appear to demonstrate an ability to understand the perspective of others, little is known about whether or not this means they recognize another individual's mental state, also known as theory of mind. Recently, in a replication study, Catala et al. (2017) helped address

whether perspective-taking can be attributed to theory of mind in dogs. Utilizing a guesser-knower paradigm, dogs preferred to follow a human-given pointing cue from a human who observed a food hiding event compared to a human who did not observe a food hiding event. This result provides further evidence that dogs attend and respond to others, in this case, humans, based on the information the humans have access to.

### Imitation

Historically, imitation has been difficult to define. While Thorndike's original definition suggested that imitation could occur without thinking, more recent definitions posit that cognitive complexity is integral for imitation to occur. Imitation is now frequently defined as the ability to learn and demonstrate a previously unknown action after observing another individual perform said action.

Considering that dogs tend to perform quite well compared to other animals on social cognition tasks, much interest has been generated over the possibility of imitation and over-imitation. One of the first studies to evaluate imitation in dogs found little evidence for imitative abilities. Kubinyi et al. (2003) had dogs observe a variety of human presented demonstrations. In one condition, the dog's owner pushed a handle to the left or right to release a ball from a box while their dog watched. Immediately after, the owner began to play with their dog and the ball. Alternatively, the dog could watch their owner touch the handle of the box (not releasing the ball), watch their owner touch the top of the box, or watch their owner not touching the box at all. Once the owner completed the demonstration, the dogs were allowed to operate the handle or the box. In the demonstration where the owner released the ball, dogs manipulated the handle more than the other conditions, but generally, the dogs moved the handle in the direction opposite than demonstrated. The authors concluded that the dogs did not perform according to imitative learning, but instead via stimulus enhancement, which led to the increased contact with the handle.

Since, Range et al. (2011b) trained dogs to open a sliding door in one of two ways, either

using their head or their paw. After watching a human demonstrator open the door, dogs were tested in two conditions. In one condition, dogs were rewarded for using the same body part as the demonstrator used. In the other, they were rewarded for using the alternative body part and not the one utilized by the demonstrator. Dogs were significantly more likely to learn the task in the first group, where the behavior rewarded matched the behavior of the demonstrator. Thus, the authors suggest that their results provide the first evidence of automatic imitation in dogs.

Additional studies have set out to discover whether dogs would imitate a human demonstrator via training methods. Topál et al. (2006) conducted a *Do-As-I-Do* task with Philip, a service dog. Philip could reproduce multiple behaviors, even novel ones, with high accuracy, performed by his trainer when given a "do it" command. Philip was also able to generalize the command when given by other demonstrators and could duplicate entire sequences of behaviors. While there are certainly limitations to the study, the first and foremost being sample size, the results suggest that because Philip was able to imitate the behaviors on observation alone he may have understood the link between his own behavior and the behavior being modeled by another. It is important to highlight that since this study, the *Do-As-I-Do* task has been conducted in larger samples to address broader questions regarding memory, social learning, imitation, training efficacy, and more.

### Impossible Task

The impossible task (also commonly called the unsolvable task) paradigm is commonly utilized to investigate social behavior. While there has been a great deal of variation across impossible task studies, including the type of apparatus used, the majority of studies present dogs with several solvable trials followed by an unsolvable trial (Mendes et al. 2021). In solvable trials, dogs are presented with obtainable reward (usually a piece of food or toy) within an apparatus. The purpose of these trials is to familiarize dogs with the possibility of obtaining the reward from the

apparatus, which may increase the reward-seeking response. Once successful in the solvable trials, the unsolvable trials are conducted. In these trials, the reward, which was previously obtainable, becomes impossible to access. In many cases, the apparatus is now “locked” shut. Depending on their question and behaviors of interest, researchers look at a variety of outcome variables, including duration of gazing, frequency of looking back, frequency of gaze alteration, latency to gaze, and persistence with the apparatus (Marshall-Pescini et al. 2009; Mendes et al. 2021; Miklósi et al. 2003).

Miklósi and colleagues were among the first to conduct the impossible task in dogs (2003). Their study used both bin-opening and rope-pulling tasks to investigate attraction to their caretaker's face during problem-solving, a precursor to communication with humans, in both dogs and wolves that were equally socialized with humans. The first six trials were easily solvable; the animal could lift the lid of a bin or pull a rope from within a cage to obtain a small piece of meat. During the unsolvable trial, the bin was mechanically secured, and the rope was tied to the cage, rendering the food inaccessible in both cases. The authors found that both dogs and wolves were equally able and motivated to complete the task in the solvable trials but that dogs looked back at their caregivers earlier and spent more time gazing at them than wolves during the unsolvable trials. The authors suggest that the difference between dog and wolf communicative behavior cannot be explained by socialization alone and is likely influenced by evolutionary and ontogenetic processes.

Marshall-Pescini et al. (2009) used a different apparatus to study whether dogs' training histories affected their performance on the impossible task. A clear plastic container was used to cover a piece of food on a wooden board (this method has since become the most commonly used apparatus in impossible task studies). The authors studied three different groups of dogs with various training experiences: agility, search and rescue, and untrained pet dogs. There were three solvable trials, during which the container could easily be overturned or moved off the platform to expose food. The container was then screwed onto the

platform during the unsolvable trial and could not be overturned or otherwise moved to expose the food. The researchers recorded the frequency of gaze alteration, gaze duration, and latency to gaze. Overall, the researchers found that these human-directed communicative behaviors were significantly affected by training experience, with search and rescue dogs exhibiting more gaze alterations between the people and the apparatus than untrained pet dogs, while agility dogs' behavior fell between these two groups.

A recent review has found many inconsistencies in methodology across unsolvable tasks (Mendes et al. 2021). To date, studies have shown that the human-directed communication behaviors of canine species are influenced by many factors, including genetics, domestication, age, training experience, and living conditions. However, as mentioned above, studies vary in the type of apparatus they used, the number of solvable trials, the length of unsolvable trials, the recorded behaviors, the human present (experimenter, caregiver, both), etc. These differences render it difficult to make meaningful comparisons across studies.

## Conclusion

In the last 30 years, researchers from fields such as animal behavior, ethology, evolutionary anthropology, psychology, sociology, economics, and more have developed a keen interest in the study of canine cognition. The reasons for this interest are multifaceted, including dogs' unique ability to understand human-given social cues and dogs' suitability as a model for human health, as well as their abundant distribution worldwide. As dog ownership increases and a general interest of dog behavior and cognition continues to develop, it can be expected that research interest within this field will do so as well. While canine cognition is currently booming, there remains much to learn about human's furry friends. The future of dog cognition is an exciting area of study as the field begins to evaluate areas such as (1) replicability and multi-lab assessments, (2) linking community science and in-lab experimentation, and

(3) assessing the suitability of ecologically relevant paradigms in connecting dog cognition to applied aspects of dog behavior.

## Synonyms

Dog communication

## Definition

Dogs may communicate with conspecifics, humans, and other domestic animals they live with. When they communicate, they use visual, auditory, olfactory, and tactile signals. Domestication has greatly changed dogs' physical appearance, and therefore, visual communication may not be equally important for dogs as for their wild relatives. Whereas some messages may be important for recognition and signaling in close proximity, others are broadcasted for long-distance communication.

## Introduction

Between the carnivores, dogs and their ancestor, wolves, can be considered as the most social. Therefore, they develop an effective communication system with an abundant number of signals to maintain cohesion of the group, no matter if that is wolf pack, human family, or a group of feral dogs (e.g., Bradshaw and Nott 1995; Feddersen-Petersen 2007). For communication and recognition in close proximity, they can use body language, body odor, touch, and certain vocal sounds. On the other hand, for distant signaling, they may leave long-term scent marks and use specific vocal sounds.

In dogs, information can be conveyed as visual, vocal, olfactory, or tactile signals, where different signaling modalities are present in different environmental conditions. Therefore, in the process of domestication, dogs have adopted new modalities of communication, those that are more suitable for life with humans in a human-made milieu (Feddersen-Petersen 2007). Indeed, in human-made environments, they need to communicate with conspecifics, humans, and other domesticated animals.

In addition, dogs are very sensitive to human social and communicative behavior (e.g., pointing gestures), as well as attention focus (e.g., they respond differently to human signals if humans have closed or opened eyes). They efficiently use information given by human companions to search for food or toys but also when they choose

to obey or to disobey (e.g., Miklósi 2007). Kaminski and Nitzschner (2013) suggest that dogs' understanding of human communication is highly specialized because of the adaptation of dogs to the specific activities they have been bred for. On the contrary, sensitivity of pet dogs to human actions and intentions may be the expression of the basic processes of conditioning as well as social and biological traits that domesticated and wild canids share rather than a special adaptation or a case of coevolution (Udell et al. 2014).

Unfortunately, because of the huge changes in dog appearance that we can see in different dog breeds, visual communication between dogs becomes challenging (Stafford 2006). Consequently, it is argued that olfactory and vocal communication become more important for dogs. Furthermore, in human-made environments, communication may occur between animals that do not live in the same household, so they can communicate only by leaving long-term olfactory messages or by vocalization, again enhancing vocal and olfactory communication over visual.

## Vocal Communication

Domestic dogs are more vocal than all other canids, and their barking can be considered as hypertrophied in comparison with wild relatives (Feddersen-Petersen 2007; Fox 1971). Because vocal communication is more important for primates, including humans, life with humans might be a reason why dogs became more vocal and developed different barking sounds (Feddersen-Petersen 2007; Miklósi 2007). Excessive barking is considered as juvenile behavior, and, in dogs, it is thought that it is associated with paedomorphosis due to domestication (Beaver 2009; Bradshaw and Nott 1995). This led to the assumption that barking is the way in which dogs communicate specifically with humans (Miklósi 2007).

From the evolutionary point of view, it seems that by differentiating their barks, dogs become more adjusted to the human environment and vocalization has become a tremendously important component of social interactions. Dogs

develop many different sounds, distinguishing them from wolves (Feddersen-Petersen 2007). For the purpose of communication, dogs may produce sounds such as barking, groaning, growling, grunting, hissing, howling, mewling, panting, puffing, screaming, tooth snapping and chattering, whining, and yelping (Beaver 2009; Bradshaw and Nott 1995). Some of those sounds are more typical of puppies: grunting, mewling, and partly screaming (Beaver 2009). Whining is considered a distress call; it may express dogs' emotional state, such as fear or pain, or it may be a way of attracting attention (Case 2010; Yeon 2007).

As suggested by Miklósi (2007), dogs can vary in at least three parameters of their bark (frequency, tonality=noise/harmony, rate), in relation to their inner state. In addition, humans are able to place the barks into the appropriate categories more often than expected by chance and therefore to associate the correct emotion with the situation. By measuring frequency and amplitude of barking, individual dogs can be distinguished, as well as their mood. Yin and McCowan (2004) recorded dog vocalizations in certain situations (e.g., disturbance, isolation, play) and found it possible to divide dogs' barks into different subtypes. In addition, humans were able to identify dogs by their bark spectrograms independent of the context of barking.

Dog breeds differ according to their frequency of barking, possibly because their tendency to bark, that is, the threshold or level of arousal required for animals to begin to bark, has been subjected to selective breeding (Fox 1971; Yeon 2007). Barking is more present in dogs living with humans, while it is comparatively rare in stray and feral dogs (Boitani and Ciucci 1995). Scientists assume that for dog-dog communication, vocalization may be less significant than other forms of signaling (Beaver 2009). Nevertheless, it seems that dogs can distinguish different barks (Maros et al. 2008). Furthermore, Simonet et al. (2005) have shown that certain vocalizations have meaning for dogs: playing dog laughter in shelters reduces unwanted distress behaviors. Finally, Adams and Johnson (1994) showed that the main reason for dogs to wake up and bark during

the night was barking of other dogs. Therefore, vocal communication may become as important as other forms of communication for dogs separated from conspecifics in nearby households, as other forms of communication demand some kind of physical contact.

In the research of Faragó et al. (2010a), three types of growling were recorded, from three different contexts: during play, guarding a bone from another dog, and reacting to a threatening stranger. Afterward, they showed a seemingly unattended bone to experimental dogs and simultaneously reproduced the recorded growling as a playback. As a result, food-guarding growls discouraged the dogs from taking away the bone more efficiently than growls recorded in the threatening stranger or the play situation. Further research (Faragó et al. 2010b) showed that dogs can extract information about the growling dog's size, meaning they were able to link the acoustic signal with the visual information provided by the dogs' pictures. Moreover, when domestic dogs perceive size-related information in growls, they adapt their behavioral response as a function of the perceived other dog's size in comparison to their own (Taylor et al. 2010).

Howling is a loud form of vocalization, and it is employed to affect companions over greater distance. In wolves, howling serves to bring individuals together, to inform rivals of pack presence, and may indicate an animal's size and aggressiveness and, thus, has a function in defending a territory (Fox 1971). Adult dogs howl in some situations, such as when some environmental sound is present (sirens, some types of music, airplanes flying overhead). Some dogs may howl when they are left alone, what resembles the social function of howling in wolves (Bradshaw and Nott 1995; Case 2010).

## Olfactory Communication

Dogs' olfactory system is tremendously more sensitive in comparison with humans. Therefore, olfactory communication has a variety of forms. Indeed, dogs have a remarkable sense of smell, i.e., they are able to detect small concentrations of

odors, and they can distinguish between them (Fox 1971). Olfactory signals may include urine and fecal droppings, ground scratching, anal sac secretions, general body odor, rubbing certain body areas against a specific object, and rolling in noxious-smelling substances (Beaver 2009; Bradshaw and Nott 1995).

Olfactory cues are used for territory marking, individual recognition, and as a method for leaving long-term messages (Fox 1971). Marks can be made on novel or familiar objects, territory, or scent marks of other individuals, or the animal may mark itself (Beaver 2009; Bekoff 2001). Unfamiliar urine, feces, or objects may be marked simply to reduce novelty (Fox 1971). In free-ranging dogs, feeding places can also be marked, probably increasing the efficiency of food source utilization (Pal 2003).

In dogs, urination and defecation have evolved into a complex behavior of territorial marking, through which one individual leaves a message about itself and acquires information about others in a given region. Dogs have preferential places for urination and defecation in their living area (Fox 1971).

In feral dogs observed by Pal (2003), females marked more frequently near the nest site after litter production and when they were in estrus. One of the messages that urine contains is about female reproductive status, and estrus females may urinate more, leaving long-distance messages for males (Case 2010). The urine of females contains a pheromone during proestrus and estrus that is attractive to males (Fox 1971). Namely, pheromones are chemical mixtures that play an important role in sexual behavior of animals. For example, a pheromone (methyl-p-hydroxybenzoate) is produced in the vagina of the female dog. The pheromones are detected by the olfactory system and the vomeronasal organ (Bubna-Littitz 2007).

Male urination can mostly be considered as scent marking (Bradshaw and Nott 1995; Pal 2003), and it is frequently accompanied by the leg-raised pattern (Fox 1971). The reason for this behavior may be that the raised-leg posture elevates the scent mark to nose height, allowing better dispersal of odor by wind, increased

evaporating surface, and minimizing the chances that the urine mark is going to be covered by snow or washed away by rain (Beaver 2009). Dogs that display raised-leg urination (RLU) may leave small quantities of urine on numerous places (Bradshaw and Nott 1995) or may deposit no urine (Pal 2003). In domestic dogs, the frequent leg-raising pattern in males is thought to be an example of behavioral hypertrophy in the domestic environment (Fox 1971). Similarly, leg-raised behavior can be observed in altered females (Bubna-Littitz 2007) but also in intact females of all smaller, more athletic breeds, where some females may even raise both back legs when urinating.

Dogs can also use defecation as marking behavior. All canids possess a pair of small glands on each side of the anal sphincter. These glands, perianal or circumanal, release some of their contents when defecation occurs (Bradshaw and Nott 1995; Fox 1971). The secretion of anal sacs is highly individual specific (Bradshaw and Nott 1995). To accentuate exposition of their communicative signal, sometimes they try to defecate on some high place, as, for example, on fences or trunks (Bubna-Littitz 2007).

Dogs show interest in their own urine and feces and that of other members of the same species. They may investigate urine or feces by sniffing and may urinate or defecate over the existing samples (Fox 1971). It is believed that dogs can extract information about the animal marked from the urine smell (Beaver 2009). Males are equally interested in urine of other males and females but over-mark more frequently on other males' urine (Bekoff 2001). In feral dogs, the leading male may urinate frequently and immediately over the urine marks of estrus females, which is termed by Pal (2003) as "possessive urine marking." Finally, dogs can distinguish between the olfactory "image" of themselves, what may be similar to mirror self-recognition in some other species (Horowitz 2017).

After urination or defecation, some canids may scratch the ground (Beaver 2009; Case 2010). In dogs, scraping with both front and hind legs may occur after urination or defecation. These behaviors may be a visual display that

attracts attention of conspecifics or a way to add odor from the paw glands after urination or defecation or may be used to mark the ground where the animal has eliminated, thus providing an additional territorial signal (Bekoff 1979; Case 2010). The probability of the occurrence of this behavior increases when the individual is aggressively aroused (Fox 1971), and it is more extensive in the presence of another dog (Bubna-Littitz 2007).

Shortly after whelping, lactating females produce the dog-appeasing pheromone (DAP) from intermammary sebaceous glands, the function of which is to calm and appease her puppies. Certain studies have shown that DAP reduces stress and anxiety in adult dogs as well, so DAP may be successfully used in veterinary clinics for the relaxation of dogs (Mills et al. 2006).

General body odor is a product of glands on the dog's feet, head, and anal region, the upper surface of the base of the tail, and between the hind legs (Bradshaw and Nott 1995). Social investigatory behavior in dogs is directed in those body areas. It starts when one dog approaches another and sniffs its head and inguinal and anal regions (Bradshaw and Nott 1995; Fox 1971).

Dogs are prone to rolling in smelly materials that they found, no matter if humans found this odor attractive or disgusting (such as carcasses of dead animals). The function of that behavior may be in collecting a desired smell or leaving their own smell (Case 2010). One possible explanation is given for wild canids, where an individual with a new smell will receive more social investigation by conspecifics after joining the pack, and that may reduce the possibility of agonistic interactions (Fox 1971).

## Visual Communication

Visual communication may include eye contact, facial expressions, ear position, tail position and movements, fur position (flat or raised), whole body postures, and movements (Bradshaw and Nott 1995; Bubna-Littitz 2007).

In dogs, eye contact can be used as a friendly greeting, but a direct stare with eyelids wide open is a threat. Although this is a subtle threat, dogs

tend to avoid eye contact when they meet the direct look of a threatening individual, to prevent further confrontation and possible injuries (Beaver 2009; Fox 1971).

In a calm dog, the mouth is relaxed and covers the teeth. In an aggressive dog, the corners of the mouth are pulled forward, and the lips are retracted vertically in snarling. As part of avoidance display, dogs may pull their lips back in a grin. Furthermore, the dog may repeatedly extrude its tongue (tongue flick) signaling intention to lick (Beaver 2009; Fox 1971), but frequent lips and nose licking can be seen in anxious dogs as appeasement signal (Mills et al. 2006). An aggressive dog may grasp the muzzle or neck of another in an inhibited bite (Beaver 2009; Landsberg et al. 2003).

In dogs, the enlarged external ears, the pinnae, have been incorporated into facial expression and may convey different motivational states. In the alert dog, the pinnae are shifted up and forward; in fear or apprehension, the ears may be flattened backward, or in greeting, ears may be flattened sideways (Fox 1971).

In dogs, the tail is used as an important visual signal, where its position and movements transfer a specific message. A tail is erected or arched when the animal is aroused, while it is lowered in unsure or anxious animals and even tucked between the legs in frightened dogs (Case 2010; Fox 1971). It may be loosely wagged for greeting or stiffly wagged in aggression. Therefore, it may be better to consider the tail wag as a context-specific behavior that may be used in different situations. Indeed, the tail may be wagged more on the right side if the dog perceives pleasing stimuli and on the left side if the dog displays withdrawal tendencies (Quaranta et al. 2007).

Whereas in wild Canidae, the coloration of the coat is adjusted to enhance visual communication, such as coloration of the face, cheeks, and tail (Fox 1971); coloration in domestic dogs depends exclusively from arbitrary breed standards set by humans. Consequently, dog breeds lost some ability for visual communication (Feddersen-Petersen 2007; Stafford 2006).

In dogs, communicative body postures play a significant role. Confident animals display a

body carriage that makes them look bigger, including rigid posture with head and tail up, or even piloerection on the hackles (Case 2010; Landsberg et al. 2003). When a dog approaches one of its own species or a human being in friendly greeting, it advances with the hind end lowered and the back arched in a “C” posture (Fox 1971). An animal may approach another and lick the corner of its mouth in greeting (Beaver 2009). Finally, a frightened dog may lie down and roll over, exposing the belly, and, if in great fear, it may urinate (Beaver 2009; Bradshaw and Nott 1995).

One communicative body posture that is used to express play intention is the “play bow.” This play-soliciting posture consists of lowering the front end of the body and raising the rear (Bekoff 1977). The whole display includes the play bow and then a quick return to a standing posture, followed by some jumping around the intended playmate. During this display, dogs may have so-called play face (Beaver 2009). When the play bow is displayed, accompanied vocalization is a call to play, but even a growl has no aggressive meaning.

Dogs’ communicative displays are complex and may include different body postures and other signals, integrated with movements. These patterns of compound signals may be seen in different contexts of dogs’ communications. For example, a dog that is showing appeasing behaviors may approach another dog with a lowered body posture, a lowered and wagging tail, squinty eyes, and a greeting grin (Case 2010). On the other hand, a more confident dog may display a ritualized attack that may be oriented in the shoulder region, the hackles, whereas the hair in that region may be erected during aggressive display (Fox 1971). Raised leg urination and ground scratching could be considered as visual signals for urine marking triggering olfactory inspection (Bekoff 1979). Finally, dogs can be in emotional conflict and show mixed signals (Beaver 2009).

As in other canids, domesticated dogs use body postures and facial expressions to communicate changes in their motivational state, their state of mind or mood (Fox 1971). Regrettably, many dog

breeds are not able to use normal visual signals due to the breeding selection of hair cover and hair type, ear carriage, and tail shape (Stafford 2006). Indeed, these breeds are obstructed from normal social interactions because they are unable to signal their intentions due to flat faces (brachycephalic), stiffed legs, very short and curled or immobile tails, drooping or erect ears, and long hair that prevents the display of piloerection on the hackles (Bradshaw and Nott 1995; Rooney 2016). Therefore, they have lost the possibility to communicate precisely due to pedomorphosis, i.e., retention of certain juvenile body features and behaviors into adulthood (Bradshaw and Nott 1995; Case 2010) and other extreme changes in morphological features (Feddersen-Petersen 2007).

There are many detrimental effects of breeding for appearance on dog behavior. For example, although horizontal and vertical lip movements can be seen, in many breeds the effectiveness of such signals is reduced because the cheeks are of the same color as the rest of the face, or covered in long hair, so the lips cannot be clearly seen (Fox 1971). Some breeds have large pendulous lips (e.g., boxers, St. Bernards) and may not be able to retract them efficiently (Beaver 2009). Furthermore, long-haired breeds cannot stare if their eyes are covered with hair (Bradshaw and Nott 1995), and this obstructed vision enhances the risk that a dog will be frightened and react fearfully. Unfortunately, the small size of some breeds may cause them to frequently suffer from fear, and thus, they may show fear-induced aggression (Beaver 2009; Rooney 2016).

In dogs, tails may be altered in comparison with wild canids. Dogs can be born with stump tails or their tails may be docked, or some may have permanently erect tails. That modification of signal structures, especially when the tail is docked and the animal is wagging the whole hind end, can have a detrimental influence on social communication (Fox 1971). Furthermore, tail docking is still performed in many countries, and, from a welfare point of view, it should be considered as a detrimental and unnecessary procedure, because it removes one of the major means of communication (Stafford 2006).

## Tactile Communication

Tactile communication is important for dogs from birth. Indeed, the sense of touch is developed before other sensory modalities are present. During the neonatal period, pups respond to tactile stimuli and probably the smell of their mother and littermates. Additionally, stimulation of the perineal region from the mother is necessary for eliminative behavior (Case 2010).

Signaling by touch may be equally important for play behavior. In research conducted by Horowitz (2008), dogs were using certain tactile play signals and attention-getting motor action patterns during play, such as putting front paws around other dogs' head, knocking other dogs with a certain part of the body, putting the nose and closed mouth to another dog, and biting or pawing at another dog's face or body.

Finally, dogs use tactile signals to get attention from their owners. For example, they may touch the owner with a nose or a paw, put the head in the owner's lap, or even try to jump in the lap regardless of their own size. Furthermore, dogs like to sleep in physical contact with the members of their family, including humans, dogs, and other pet animals.

## Canine Behavioral and Welfare Problems due to Incomplete Understanding of Communication

Most of the behavioral problems that are considered as a nuisance for owners are normal canine behaviors. For example, owners are disturbed by the quantity of dogs barking, especially in the urban environment. Whereas barking is not equally present in all dog breeds, it is a part of standard behavioral repertoire and, as such, cannot be completely stopped. Alternatively, a dog debarking, i.e., surgical reduction of tissue in the vocal chords, is a welfare issue. Debarked dogs are still trying to bark but cannot produce a sound, so they might be frustrated. On the other hand, many dogs if not debarked may end up in a shelter or euthanized (Beaver 2009). Barking noise is a special problem in shelters as well (Coppola et al. 2006).

In addition, many fundamental social communication behaviors of dogs are considered unacceptable by owners, for example, smelling the perineal region or licking the lips of humans (Stafford 2006). An example of misunderstanding between humans and dogs is when dogs are jumping on people while trying to greet them. Also, dogs' attempts to lick human faces could be considered unpleasant, so dogs might be disciplined (Beaver 2009; Case 2010). Punishing a dog for expressing happiness and love to its owner may harm the dog emotionally.

Although having a specific body odor may be a matter of self-identity for dogs (Horowitz 2017), hygienic owners wash their dogs too frequently. Furthermore, some anthropomorphic owners prevent their dogs from olfactory communication that includes smelling of another dog's back or urine and feces on the street. By preventing dogs from normal communication patterns, they seriously reduce the dog's quality of life.

Finally, dogs' visual communication is extremely changed due to the creation of different breeds. We can only scratch the surface of the problem because most purebred dogs live in human-made environments where humans control most of dogs' social interactions and, thus, prevent problems caused by misinterpretation of communicative signals.

## Conclusion

Dogs are amazing in their communication flexibility, i.e., they communicate successfully with conspecifics, humans, and other domestic species. Whereas their life has been changing from being wolves to human companions, from hunters to pets, they have succeeded to adapt their communication repertoire. Their social abilities continue to be discovered, along with the ways they use human signaling systems to harmonize their behavior with human companions.

However, many communicative behaviors are prevented by owners as well due to dogs' physical appearance. Therefore, the normal behavior of the dog might best be understood in research of feral or wild dogs like the dingo (Stafford 2006).

More knowledge of dogs' social cognition and communication modalities should create better lives for dogs and enhance their welfare.

## Canine Diet

Jacqueline Boyd

Skinner's Pet Foods, Stradbroke, UK

## Synonyms

[Canine feeding](#); [Canine food intake](#); [Food preference](#); [Nourishment](#)

## Definition

Canine diet refers to the food intake by members of the Canidae family. Dietary intake and choices of canids are closely aligned to their behavioral, dental, anatomical, and physiological characteristics associated with ingestion, digestion, absorption, and elimination. In addition, the spatial and temporal availability of feedstuffs will impact on dietary intake and preferences. The diversity of members of the Canidae family results in a variety of potential diets, most notably observed in the domestic dog, *Canis lupus familiaris*, where human intervention and management typically regulates dietary choices and intake, occasionally in conflict with the nutritional needs of the species. For wild and free-living canids, diet is more closely impacted by typical ecological pressures such as seasonality, prey density, predator population density, intra- and interspecies relationships, and, increasingly, anthropogenic effects.

## Introduction

The mammalian family Canidae, belongs to the order Carnivora and includes three subfamilies, two of which are extinct (the Borophaginae and Hesperocyoninae) and the extant Caninae (Miklosi 2015). Members of the Caninae are known as canines and include wolves, foxes, jackals, the domestic dog, and several other species, typically described as “dog-like.” The domestic dog is notable within the Caninae subfamily, as a species that typically occupies similar ecological niches to humans and has a diet typically representative of that shared niche. This is in addition to demonstrating some evolutionary changes suggestive of adaptation to dietary provision within that niche (Axelsson et al. 2013), alongside other genetic and behavioral signatures of convergent evolution (Udell and Wynne 2008). Indeed, the domestic dog is acknowledged to be one of the earliest domesticated species and remains one of the most commonly kept domestic animals globally. This has significant consequences for their diet.
